The behaviour of subluminous X-ray transients near the Galactic centre as observed using the X-ray telescope aboard Swift

N. Degenaar and R. Wijnands

_Astronomy & Astrophysics, 2009, 495, 547_

Abstract – In this paper we report on the spectral analysis of seven X-ray transients, which were found to be active during a monitoring campaign of the Galactic centre carried out in 2006–2007, using the X-ray telescope aboard the _Swift_ satellite. This campaign detected new outbursts of five known X-ray transients and discovered two new systems. Their 2–10 keV peak luminosities range from $\sim 10^{34}$ to $6 \times 10^{36}$ erg s$^{-1}$. Two of the sources discussed in this paper are confirmed neutron star systems (AX J1745.6–2901 and GRS 1741–2853), while the five others have an unknown nature. We discuss the characteristics of the observed outbursts and the duty cycles of the various systems. We detected two type-I X-ray bursts with a duration of 50–60 s from AX J1745.6–2901, which we discuss in view of the bursting behaviour of low-luminosity X-ray transients. Assuming that we are dealing with accreting neutron stars and black holes, we estimate the time-average accretion rate, $\langle M_{\text{long}} \rangle$, of the transients, which is an important input parameter for binary evolution calculations. Our estimates lie in the range of $3 \times 10^{-13}$ M$_\odot$ yr$^{-1} \lesssim \langle M_{\text{long}} \rangle \lesssim 1 \times 10^{-10}$ M$_\odot$ yr$^{-1}$, if the systems are neutron star X-ray binaries and between $4 \times 10^{-14}$ M$_\odot$ yr$^{-1} \lesssim \langle M_{\text{long}} \rangle \lesssim 2 \times 10^{-11}$ M$_\odot$ yr$^{-1}$ for a scenario where the accreting object is a black hole.
5 Swift observations of subluminous X-ray transients located near the Galactic centre

5.1 Introduction

Our Galaxy harbours many X-ray transients that spend most of their time in a dim, quiescent state, but occasionally they experience bright X-ray outbursts (typically lasting weeks to months) during which their X-ray luminosity increases by more than a factor of 100. Many of these transient X-ray sources can be identified with compact objects (neutron stars or black holes) accreting matter from a companion star. In such systems, the X-ray outbursts are ascribed to a sudden strong increase in the accretion rate onto the compact object. X-ray transients can be classified based on their 2–10 keV peak luminosity, $L_{\text{peak}}^{\text{X}}$. The bright X-ray transients ($L_{\text{peak}}^{\text{X}} \sim 10^{37}$–$10^{39}$ erg s$^{-1}$) have been known and extensively studied since the early days of X-ray astronomy. However, in the past decade it became clear that a group of subluminous X-ray transients ($L_{\text{peak}}^{\text{X}} \lesssim 10^{37}$ erg s$^{-1}$) also exists, where the distinction is made between faint ($L_{\text{peak}}^{\text{X}} \sim 10^{36}$–$10^{37}$ erg s$^{-1}$, e.g., Heise et al. 1999; in’t Zand 2001) and very-faint ($L_{\text{peak}}^{\text{X}} \sim 10^{34}$–$10^{36}$ erg s$^{-1}$, e.g., Sidoli et al. 1999; Porquet et al. 2005b; Muno et al. 2005b; Wijnands et al. 2006a) systems. Although the faint to very faint X-ray transients exhibit qualitatively different behaviour than the brighter systems (e.g., Cornelisse et al. 2002; Okazaki & Negueruela 2001; King 2000), this classification based on peak luminosities is not strict and hybrid systems are known to exist (e.g., Wijnands et al. 2002b).

In particular the study of very-faint X-ray transients (VFXTs) is hampered by the sensitivity limitations of X-ray instruments, and consequently their nature is not understood well. To date, about 30 members are known, most of which are found very close to Sgr A$^*$ (within $\sim 10''$; Muno et al. 2005b), but this might be a selection effect due to all the high-resolution X-ray observations in this region. Several VFXTs were found at larger distances from Sgr A$^*$ as well (e.g., Hands et al. 2004; Heinke et al. 2009a). A significant fraction ($\sim 1/3$) of the VFXTs have exhibited type-I X-ray bursts (e.g., Cornelisse et al. 2002) and can thus be identified with neutron stars accreting matter from, most likely, a low-mass (i.e., $M \lesssim 1\,M_\odot$) companion. The low outburst luminosities characteristic of VFXTs combined with what is known about their duty cycles, imply that these low-mass X-ray binaries (LMXBs) have very low time-averaged mass accretion rates, which could challenge our understanding of their evolution (King & Wijnands 2006).

There might also be other types of sources that can produce subluminous X-ray outbursts. It is conceivable that some systems are compact objects that are transiently accreting at a very low level from the strong stellar wind of a high-mass star or the circumstellar matter around a Be star (e.g., Okazaki & Negueruela 2001). In addition,

\footnote{All fluxes and luminosities quoted in this paper are for the 2–10 keV energy band, unless otherwise stated.}
5.2 Observations and data analysis

Some strongly magnetised neutron stars ($B \sim 10^{14} - 10^{15}$ G, magnetars) are observed to experience occasional X-ray outbursts with peak luminosities of $\sim 10^{35}$ erg s$^{-1}$ (Ibrahim et al. 2004; Muno et al. 2007a) and can thus be classified as VFXTs. The cause of their outbursts is unknown, but is likely related to magnetic field decay (e.g., Ibrahim et al. 2004). Furthermore, Mukai et al. (2008) recently pointed out that classical novae can be visible as 2–10 keV X-ray sources with luminosities in the range of a few times $10^{34} - 10^{35}$ erg s$^{-1}$ for weeks to months (see figure 1 of Mukai et al. 2008). The X-ray emission is thought to emerge from shocks within the matter that is ejected during the nova.

Here we present the analysis of seven X-ray transients, that were found active during a monitoring campaign of the Galactic centre (GC) by the X-ray telescope (XRT) aboard the Swift satellite (Kennea & The Swift/XRT team 2006), carried out in 2006 and 2007.

### 5.2 Observations and data analysis

The GC was monitored almost daily with the XRT aboard Swift, from 2006 February 24 until 2007 November 2, with exclusion of the epochs from 2006 November 3 till 2007 March 6 (due to Solar constraints) and 2007 August 11 till September 26 (due to a safe-hold event; Gehrels 2007). Each Swift/XRT pointing typically lasted $\sim 1$ ks, although occasionally longer exposures (up to $\sim 13$ ks) were carried out. Most of the data was collected in photon counting (PC) mode, albeit sometimes an unusual high count rate (due to the occurrence of a type-I X-ray burst) induced an automated switch to the windowed timing (WT) mode. We obtained all observations of 2006–2007 GC monitoring campaign from the Swift data archive.

The XRT data were processed with the task xrtpipeline using standard quality cuts and event grades 0–12 in PC mode (0–2 in WT mode). We searched the data for transient X-ray sources by comparing small segments of Swift data, spanning $\sim 5$ ks, with one another. We found a total of seven different X-ray transients with peak luminosities $\gtrsim 10^{34}$ erg s$^{-1}$. The source coordinates and associated uncertainties of the detected transients were found by running the XRT software task xrtcentroid on the data. The results are listed in Table 5.1. A source was considered in quiescence when it was not detected within a data bin of approximately 5 ks by visual inspection. The unabsorbed 2–10 keV flux corresponding to this threshold depends on the assumed spectral model, but is roughly $2 \times 10^{-13}$ erg cm$^{-2}$ s$^{-1}$. This translates into a luminosity of $\sim 1.5 \times 10^{33}$ erg s$^{-1}$ for a distance of 8 kpc.

Figure 5.1 shows two 0.3–10 keV images of the Swift/XRT campaign, which

covered a total field of $\sim 26' \times 26'$ of sky around Sgr A* (note that individual pointings have a smaller field of view, FOV). Figure 5.1 displays a merged image of all PC mode observations carried out in 2006 and 2007. Apart from many persistent X-ray sources and strong diffuse emission around Sgr A*, it shows six different X-ray transients with peak luminosities $\gtrsim 10^{34}$ erg s$^{-1}$ (listed in Table 5.1). Figure 5.1 also includes a magnified image of the inner region around Sgr A*, taken from the epoch 2006 June 30 till November 2. This was the only episode during the entire 2006–2007 Swift monitoring campaign in which AX J1745.6–2901 was not active, and a seventh active transient, CXOGC J174535.5–290124, could be detected. CXOGC J174535.5–290124 and AX J1745.6–2901 are so close together, that Swift cannot spatially resolve both sources when the latter, which is the brighter of the two, is active. Apart from CXOGC J174535.5–290124, this image also shows CXOGC
5.2 Observations and data analysis

Figure 5.1: X-ray images (0.3–10 keV) of the GC obtained with Swift/XRT (North is up and East is to the right). Left: Merged image of all PC mode observations carried out in 2006 and 2007. The known X-ray transients AX J1745.6–2901, CXOGC J174540.0–290005, GRS 1741–2853 and XMM J174457–2850.3, as well as the newly discovered subluminous X-ray transients Swift J174553.7–290347 and Swift J174622.1–290634 can be seen in this image. Right: Magnified image of the inner region around Sgr A* of the epoch 2006 June-November, during which CXOGC J174535.5–290124 and CXOGC J174540.0–290005 were both detected in an active state. The Swift/XRT position for AX J1745.6–2901 is also plotted, to show that the active object does not coincide with the coordinates of AX J1745.6–2901 and is in fact a distinct source.

J174540.0–290005, which lies North of Sgr A*.

We extracted source lightcurves and spectra (using XSELECT v. 2.3) from the event lists using a circular region with a radius of 10 or 15 pixels (the largest regions were used for the brightest sources). Spectra were extracted only from the data in which a source was active, whereas lightcurves were constructed from all data where a source was in FOV. Corresponding background lightcurves and spectra were averaged over a set of three nearby source-free regions, each of which had the same shape and size as the source region. For none of the transients it was possible to use an annulus for the background subtraction, either because the objects were too close to the edge of the CCD or using an annular background region would encompass too much contamination from nearby X-ray sources or diffuse emission around Sgr A*. The spectra were grouped using the FTOOL GRPPHA, to contain bins with a minimum of 20 photons.

Exposure maps were generated with XRTEXPOMAP to correct the spectra for fractional exposure loss due to bad columns on the CCD (Abbey et al. 2006). The generated exposure maps were used as input to create ancillary response files (arf) with XRTMKARF. We used the latest versions of the response matrix files (v. 10; rmf) from the CALDB database. For the brightest of the seven transients, AX J1745.6–2901 and GRS 1741–2853, the 2007 PC mode data was affected by pile-up. We attempted

Note.— The quoted position uncertainties (1σ) were calculated by taking the square root of the quadric sum of the statistical error (from the *wavdetect* routine) and the uncertainty in absolute astrometry (0.6″; Aldcroft et al. 2000).

to correct for the consequent effect on spectral shape and loss in source flux by the same methods as described by Vaughan et al. (2006).\(^5\)

Using Xspec (v. 11; Arnaud 1996), we fitted all grouped spectra with a powerlaw continuum model modified by absorption. From these fits we deduce the 2–10 keV mean unabsorbed outburst flux for each source and combined this with the average 2–10 keV *Swift*/XRT count rate of the outburst to infer a flux-to-count rate conversion factor. This factor was then used to determine the 2–10 keV unabsorbed peak flux for each source from the maximum count rate observed.

5.2.1 Chandra data

To obtain more accurate position information for the X-ray transients, we searched for *Chandra* archival data of the time the transients were in outburst. We found several *Chandra* observations at times when our seven *Swift* transients were active (see Table 5.2). We analysed these *Chandra* data using the ciao tools (v. 4.0) and the standard *Chandra* analysis threads.\(^6\) The *Chandra* source positions and associated errors were determined using the tool *wavdetect* and are also listed in Table 5.2.

5.2.2 Time-averaged accretion rates

Assuming that the observed transients are accreting neutron stars or black holes in X-ray binaries, we can estimate the mean accretion rate during an outburst, ⟨\(\dot{M}_{\text{ob}}\)⟩, from the mean unabsorbed outburst flux. Following in’t Zand et al. (2007), we apply a correction factor of 3 to the mean 2–10 keV outburst luminosity (unabsorbed, inferred from spectral fitting) to obtain the 0.1–100 keV accretion luminosity \(L_{\text{acc}}\) (which is an approximation of the bolometric luminosity of the source).

---

\(^5\)See also http://www.swift.ac.uk/pileup.shtml.
\(^6\)Listed at http://asc.harvard.edu.
The mass-accretion rate during outburst is then estimated by employing the relation \( \langle \dot{M}_{\text{ob}} \rangle = \frac{R L_{\text{acc}}}{GM} \), where \( G = 6.67 \times 10^{-8} \text{ cm}^3 \text{ g}^{-1} \text{ s}^{-2} \) is the gravitational constant. We adopt \( M = 1.4 \ M_{\odot} \) and \( R = 10 \text{ km} \) for a neutron star accretor and \( M = 10 \ M_{\odot} \) and \( R = 30 \text{ km} \) for the scenario of a black hole primary. Presuming that the observed outburst is typical, we convert the mass-accretion rate during outburst to a long-term averaged value, \( \langle \dot{M}_{\text{long}} \rangle \), by using the relation \( \langle \dot{M}_{\text{long}} \rangle = \langle \dot{M}_{\text{ob}} \rangle \times t_{\text{ob}} / t_{\text{rec}} \), where \( t_{\text{ob}} \) is the outburst duration and \( t_{\text{rec}} \) is the system’s recurrence time, i.e., the sum of the outburst and quiescence time scales. The factor \( t_{\text{ob}} / t_{\text{rec}} \) represents the duty cycle of the system.

The calculation of the time-averaged accretion rate, as described above, is subject to several uncertainties. Both the translation from the observed 2–10 keV luminosity to the bolometric luminosity, as well as the conversion to the mass-accretion rate are uncertain (the exact efficiency of converting gravitational potential energy to X-ray radiation is unknown). Furthermore, many X-ray transients show irregular outburst- and recurrence times, which makes it difficult to estimate their duty cycles and what we observe over the course of a few years may not be typical for their long-term accretion history. However, the quasi-daily Swift monitoring observations of 2006–2007 provide an unique insight in the outburst behaviour of these subluminous transients, allowing for a better estimate of their duty cycles than would be possible based on single, randomly spaced pointings alone. With the method described above, we can at least get an order of magnitude estimate of their time-averaged accretion rates.

An important caveat is that accretion flows around low luminosity (below a few percent of Eddington) black holes might be radiative inefficient (e.g., Blandford & Begelman 1999; Narayan & McClintock 2008). If this is the case, the mass-accretion rate as inferred from the X-ray luminosity can be severely underestimated. Thus, in particular the values inferred for the black hole scenario should be considered with caution (see Section 5.4.5).

### 5.3 X-ray lightcurves and spectra

The background corrected lightcurves of the seven transients are displayed in Figure 5.2 and their spectra are plotted in Figure 5.3. The X-ray properties of each individual source will be discussed below; a summary of the spectral parameters for all sources can be found in Table 5.3. All detected transients were heavily absorbed \( (N_H \gtrsim 6 \times 10^{22} \text{ cm}^{-2}) \), consistent with what is observed for sources close to Sgr A*. Therefore, throughout this paper we assume a distance of 8 kpc for all detected transients when calculating their 2–10 keV X-ray luminosities.
Figure 5.2: Background-corrected Swift/XRT lightcurves of the transients that were active during the Swift monitoring campaign of the GC in 2006 and 2007. During days 252–374 after the start of the survey (2006 February 24), no observations were carried out due to Solar constraints. In between days 533–579, all Swift’s instruments were off-line due to a safe-hold event (Gehrels 2007). We could only deduce information on the activity of CXOGC J174535.5–290124 from Swift observations at times that the nearby, brighter transient AX J1745.6–2901 was not active. This was the case from 2006 late-June till early-November, so the lightcurve of CXOGC J174535.5–290124 only covers this epoch.
Figure 5.2: Continued. – Swift J174622.1–290634, GRS 1741–2853 and XMM J174457–2850.3 were not always in FOV of the observations, so lightcurves of these three sources contain more data gaps than that of the other transients. The plot of GRS 1741–2853 includes a zoom in of a small outburst that occurred in 2006.
Figure 5.3: Swift/XRT background-corrected spectra of the seven X-ray transients that were found to be active during the Swift monitoring campaign of the field around Sgr A* in 2006 and 2007. The absorbed powerlaw model fit is plotted along with the data points for each source. For AX J1745.6–2901 three different spectra are shown: the average outburst spectrum of 2007 (upper), 2006 (middle) and the quiescent spectrum (lower) observed by Muno et al. (2004). For the calculation of the average 2006 spectrum, we removed the two observations in which type-I X-ray bursts were detected. The plot of Swift J174553.7–290347 includes the X-ray spectrum of CXOGC J174553.8–290346 (from Muno et al. 2004), which possibly represents the quiescent state of this transient. GRS 1741–2853 displayed separate outbursts in 2006 and 2007; average spectra of both outbursts are shown.

Note.– All quoted fluxes are for the 2–10 keV band and given in units of $10^{-12}$ erg cm$^{-2}$ s$^{-1}$. The X-ray luminosities, given in units of $10^{34}$ erg s$^{-1}$, are calculated from the unabsorbed 2–10 keV fluxes assuming a distance of 8 kpc for all sources. The fluxes and luminosities of XMM J174457–2850.3 were deduced using XMM, with $N_H$ and $\Gamma$ fixed at the values obtained by Sakano et al. (2005). The hydrogen column density is given in units of $10^{22}$ cm$^{-2}$.

5.3.1 AX J1745.6–2901

The start of the Swift/GC monitoring observations in 2006 immediately revealed the new X-ray transient Swift J174535.5–290135, which is located $\sim$ 1.5$\arcmin$ SE from Sgr A* (Kennea et al. 2006a). This X-ray source remained active for approximately 16 weeks until it returned to quiescence in 2006 late-June. Renewed activity of the system was reported in 2007 February (Wijnands et al. 2007; Kuulkers et al. 2007a), and the Swift/GC monitoring observations suggest that it remained as such for more than a year, as it was active until the campaign ended in 2007 November (see Figure 5.2). We note that the monitoring campaign continued in 2008 and that the source was detected throughout 2008. However, a detailed discussion of those observations are beyond the scope of our paper. The detection of eclipses with an 8.4-h period seen in XMM-Newton observations (Porquet et al. 2007), positively identify Swift J174535.5–290135 with the ASCA detected eclipsing X-ray burster AX J1745.6–
2901 (Maeda et al. 1996). In addition, the Chandra position of AX J1745.6–2901 (see Table 5.2) is consistent with that of the X-ray source CXOGC J174535.6–290133 (Muno et al. 2003b), which likely represents the quiescent counterpart of the system.

Figure 5.2 displays the activity of AX J1745.6–2901 during the 2006–2007 Swift campaign. In 2006, the outburst reached a peak luminosity of $9.2 \times 10^{35}$ erg s$^{-1}$, while the average outburst luminosity was $3.9 \times 10^{35}$ erg s$^{-1}$ (both in the 2–10 keV energy band). For an outburst duration of at least 16 weeks (AX J1745.6–2901 might have been active before the start of the Swift monitoring campaign), we can deduce a fluence of $\gtrsim 1.8 \times 10^{-4}$ erg cm$^{-2}$ s$^{-1}$. In 2007, the system was active again, but with an higher average luminosity of $1.6 \times 10^{36}$ erg s$^{-1}$ and a reached peak value of $6.1 \times 10^{36}$ erg s$^{-1}$ (both 2–10 keV). Different outburst luminosities have been reported for AX J1745.6–2901 in the past; in 1993 October the source was detected at a luminosity of $2 \times 10^{35}$ erg s$^{-1}$, while in 1994 October it became as bright as $9 \times 10^{35}$ erg s$^{-1}$ (both values are in the 3–10 keV band, Maeda et al. 1996).

Before and after the 6-week epoch in 2007 that the Swift observatory was offline due to a safe-hold event (Gehrels 2007, this corresponds to days 533-579 in the lightcurves displayed in Figure 5.2), AX J1745.6–2901 was active at similar count rates. We have inspected proprietary XMM-Newton data of the GC performed on 2007 September 6 (see Chapter 7), i.e., halfway the interval that the Swift observatory was offline. AX J1745.6–2901 was clearly detected during that observation, which demonstrates that the source remained active all through the 2007 Swift monitoring campaign. For an outburst duration of 34 weeks, the 2–10 keV fluence of the 2007 outburst is then $5.7 \times 10^{-3}$ erg cm$^{-2}$. However, this inferred value should be considered a lower limit, since we also found AX J1745.6–2901 to be active during all Swift/GC monitoring observations in 2008, at a flux similar to that of 2007 (the source was also reported active during Chandra observations carried out in 2008, see Heinke et al. (2008) and Degenaar et al. (2008a)). This suggests that the outburst observed in 2007, continued in 2008 and thus has a duration of at least 1.5 years. For that outburst length, the fluence increases to $6.5 \times 10^{-3}$ erg cm$^{-2}$ (2–10 keV), and will become even larger if the outburst continues.

Between 1999 and 2002, the GC was observed several times with Chandra (Muno et al. 2003b, 2004). Thus, if the observed long outburst duration of AX J1745.6–2901 is typical, the source likely resided in quiescence for at least 4 years. However, the quiescent time scale must be less than 13 years, the time since the ASCA discovery (Maeda et al. 1996). Estimating the long-term time-averaged mass-accretion rate for AX J1745.6–2901 is difficult due to the different outburst durations and luminosities the system displays. To get a rough estimate, we will assume that an outburst duration of 1.5 years and a 2–10 keV outburst luminosity of $2 \times 10^{36}$ erg s$^{-1}$ are typical for the source. The duty cycle of this neutron star system then ranges from 10% for...
5.3 X-ray lightcurves and spectra

$t_q \sim 13$ yr up to 30% for $t_{\text{rec}} \sim 4$ yr. This results in an estimated long-term time-averaged accretion rate of $\sim (5 - 15) \times 10^{-11} \, M_\odot \, \text{yr}^{-1}$ (see Table 5.4). This value might be a lower limit, since AX J1745.6–2901 possibly exhibited more outbursts like the smaller one observed in 2006. On the other hand, the observed long outburst of 1.5 years might not be typical for the system, in which case this estimate would be an upper limit on the time-averaged mass-accretion rate.

To compare the outburst spectrum of AX J1745.6–2901 with the likely quiescent counterpart of the source (CXOGC J174535.6–290133), we downloaded the reduced data of the Chandra monitoring campaign that are made available online.\footnote{Available at http://www.astro.psu.edu/users/niel/galcen-xray-data/galcen-xray-data.html (Muno et al. 2004).} After the spectrum was grouped to contain at least 20 photons per bin, we fitted it with an absorbed powerlaw model with the hydrogen column density fixed at the 2006 outburst value ($N_H = 23.1 \times 10^{22} \, \text{cm}^{-2}$). This resulted in a powerlaw index of $\Gamma = 1.8 \pm 0.5$ and an unabsorbed 2–10 keV flux of $(7.7 \pm 0.4) \times 10^{-14} \, \text{erg cm}^{-2} \, \text{s}^{-1}$. The inferred 2–10 keV luminosity is $5.9 \times 10^{32} \, \text{erg s}^{-1}$. The quiescent spectrum is plotted in Figure 5.3 along with the average outburst spectra of 2006 and 2007.

**Type-I X-ray bursts**

The Swift/GC monitoring observations detected two type-I X-ray bursts from AX J1745.6–2901. The times at which these bursts occurred are indicated in Figure 5.2. The first burst was observed on 2006 June 3 and had an exponential decay time scale of $\sim 10$ s (see Figure 5.4). Due to the sudden increase in count rate associated with the X-ray burst, the XRT instrument automatically switched from PC to WT mode. There is no burst data available during this switch, which took about 3 s. We extracted the spectrum of the first 3 s of the observed burst peak and fitted it to an absorbed blackbody model with the hydrogen column density fixed at $N_H = 23.1 \times 10^{22} \, \text{cm}^{-2}$, the value inferred from the mean outburst spectrum of 2006. This yielded $kT = 1.7^{+1.9}_{-1.6}$ keV and a radiating surface area of $10^{12} \, \text{km}$ (assuming $D = 8$ kpc). The 0.01–100 keV peak flux inferred from our spectral fit is $1.3^{+0.1}_{-0.1} \times 10^{-8} \, \text{erg cm}^{-2} \, \text{s}^{-1}$ (corrected for absorption), which translates into an observed peak luminosity of $9.6 \times 10^{37} \, \text{erg s}^{-1}$. However, the true burst peak was likely missed due to the automatic switch of XRT modes. If we extrapolate the burst lightcurve to the time $t = -3$ s (i.e., the time of the mode-switch), we can deduce a 0.01–100 keV peak luminosity of $1.3 \times 10^{38} \, \text{erg s}^{-1}$. Although the true peak of the type-I X-ray bursts will remain uncertain, it is clear that it likely was close to the Eddington luminosity for a neutron star ($2.0 \times 10^{38} \, \text{erg s}^{-1}$ for a hydrogen-rich and $3.8 \times 10^{38} \, \text{erg s}^{-1}$ for a hydrogen-poor photosphere; e.g., Kuulkers et al. 2003).
Another burst was observed on 2006 June 14, which had an exponential decay time scale of $\sim 20$ s (see Figure 5.4). This time, no automated switch of XRT modes occurred, so that the burst was fully detected in the PC mode. Due to the high count rate associated with the burst, the PC image was severely piled-up and a proper spectral fitting of the burst peak was not possible. Therefore, we used the burst count rate to find the peak flux and luminosity. To obtain the correct count rates, the observed ones have to be corrected for the loss in photons caused by bad columns and pixels using an exposure map, and a pile-up correction needs to be applied. For the latter, we extracted the source photons from an annular source region, avoiding the piled-up inner pixels. We determined the proper correction factor for the observed PC count rate following analysis threads on the Swift webpages. This way, we found that the burst must have reached a peak count rate of 15 cnts s$^{-1}$ in the PC mode. Employing rmmss with a hydrogen column density of $N_H = 23.1 \times 10^{22}$ cm$^{-2}$ (the 2006 outburst value) and temperatures of $kT = 1.0 - 3.0$ keV (roughly the range inferred for the first burst), we can estimate an unabsorbed 0.01–100 keV flux of $(0.68 - 1.0) \times 10^{-8}$ erg cm$^{-2}$ s$^{-1}$. The corresponding 0.01–100 keV peak luminosity is $(0.52 - 1.1) \times 10^{38}$ erg s$^{-1}$, i.e., comparable to the X-ray burst that occurred on 2006 June 3.
5.3.2 CXOGC J174535.5–290124

By the beginning of 2006 August, a transient was detected in outburst approximately 1.3′ SE from Sgr A∗. The XRT position for this source, which is listed in Table 5.1, is only ∼ 14″ away from the above discussed AX J1745.6–2901, which had returned to quiescence a month earlier. We obtained an improved position for this transient from an archival Chandra observation performed on 2006 August 22 (see Table 5.2) and find that its coordinates are not consistent with the Chandra position of AX J1745.6–2901 (Table 5.2), but do coincide with that of the known X-ray transient CXOGC J174535.5–290124 (Muno et al. 2005b).

CXOGC J174535.5–290124 is a subluminous X-ray transient that was discovered during a Chandra campaign of the GC (Muno et al. 2004). Whereas the source was not detected in 1999 and 2000 (yielding a 2–8 keV upper limit for the quiescent luminosity of $L_X < 9 \times 10^{30}$ erg s$^{-1}$; Muno et al. 2005b), it was found in outburst with Chandra on several occasions between 2001 and 2005, displaying typical 2–8 keV luminosities of $10^{33} - 34$ erg s$^{-1}$ (Muno et al. 2005b; Wijnands et al. 2005c; Degenaar et al. 2008a). The source was also detected in outburst during XMM-Newton observations obtained in September 2006, when it displayed a 2–10 keV X-ray luminosity of $2 \times 10^{34}$ erg s$^{-1}$ (Wijnands et al. 2006b). This is in agreement with the 2006 Swift data of CXOGC J174535.5–290124 (see Table 5.3), which showed an average outburst luminosity of $1.7 \times 10^{34}$ erg s$^{-1}$ and an observed peak luminosity of $3.0 \times 10^{34}$ erg s$^{-1}$ (both in the 2–10 keV energy band). The source was observed in outburst until the Swift observations stopped in November 2006. The outburst of late 2006 thus had a duration of at least 12 weeks. This yields a lower limit on the outburst fluence of $1.6 \times 10^{-5}$ erg cm$^{-2}$ s$^{-1}$ in the 2–10 keV energy band.

The nearby transient AX J1745.6–2901 is typically a factor 10–100 brighter during outburst than CXOGC J174535.5–290124, and due to their small separation, we cannot deduce any information on CXOGC J174535.5–290124 from Swift data when AX J1745.6–2901 is active. However, Chandra does have the required spatial resolution to separate these two transients, even when AX J1745.6–2901 is in outburst. Inspection of archival Chandra data of both 2006 and 2007 revealed that CXOGC J174535.5–290124 was in outburst simultaneously with AX J1745.6–2901 in 2006 April (Obs ID 6639), although it was not active during Chandra observations carried out in 2006 May, June and early-July. Thus, CXOGC J174535.5–290124 must have returned to quiescence by the end of 2006 April, but it reappeared in 2006 August, when Swift detected the source. Since AX J1745.6–2901 was continuously active during the Swift/GC monitoring observations of 2007, we cannot deduce any information on the activity CXOGC J174535.5–290124 from the 2007 Swift data. However, the source is found active Chandra data obtained in 2007 March, April and May (Degenaar et al. in prep.; see Chapter 7). In 2008, CXOGC J174535.5–290124 is re-
ported active during pointed Chandra/HRC-I observations performed on May 10-11 (Degenaar et al. 2008a). During that observation the 2–10 keV X-ray luminosity was approximately $2 \times 10^{33}$ erg s$^{-1}$, i.e., a factor of 10 below the outburst level detected with Swift in 2006.

Despite its low peak luminosity, CXOGC J174535.5–290124 appears to be active quite regularly. However, its duty cycle is not completely clear; the Swift observations show that in 2006 the system was in quiescence for about 3 months in between two outbursts. Tentatively assuming a recurrence time of 3–12 months and a typical outburst duration of 12 weeks, the duty cycle for CXOGC J174535.5–290124 is $\sim 20$ – 50%. The various detections of CXOGC J174535.5–290124 vary between a few times $10^{33}$–$10^{34}$ erg s$^{-1}$, so we adopt a mean 2–10 keV outburst luminosity of $1 \times 10^{34}$ erg s$^{-1}$. This results in a long-term averaged accretion rate of $5 \times 10^{-13} \text{M}_\odot \text{yr}^{-1} \lesssim \langle \dot{M}_{\text{long}} \rangle \lesssim 1 \times 10^{-12} \text{M}_\odot \text{yr}^{-1}$ for a neutron star primary or $7 \times 10^{-14} \text{M}_\odot \text{yr}^{-1} \lesssim \langle \dot{M}_{\text{long}} \rangle \lesssim 2 \times 10^{-13} \text{M}_\odot \text{yr}^{-1}$ in case of a black hole accretor (see Table 5.4).

5.3.3 CXOGC J174540.0–290005

In 2006 late-October Kennea et al. (2006c) reported on activity from an X-ray transient, Swift J174540.2–290005, located $\sim 20''$ N from Sgr A*. In an archival Chandra observation performed on 2006 August 22, we find one X-ray source within the XRT error radius of Swift J174540.2–290005 (see Table 5.1). The Chandra position of this source (see Table 5.2) is consistent with that of CXOGC J174540.0–290005 (Muno et al. 2005b), positively identifying Swift J174540.2–290005 with this Chandra-discovered X-ray transient. CXOGC J174540.0–290005 was detected in outburst only once before, in 2003, when it displayed a luminosity of $3.4 \times 10^{34}$ erg s$^{-1}$ (2–8 keV, Muno et al. 2005b). This is a factor of a few lower than the peak luminosity of $2.3 \times 10^{35}$ erg s$^{-1}$ that was detected by Swift in 2006 (2–10 keV, see Table 5.3). Muno et al. (2005b) derived an upper limit for the quiescent luminosity of this system of $< 4 \times 10^{34}$ erg s$^{-1}$ (2–8 keV).

The 2006 outburst of CXOGC J174540.0–290005 lasted almost 2 weeks, and the inferred outburst fluence is $1.3 \times 10^{-5}$ erg cm$^{-2}$ (2–10 keV). No other outburst from CXOGC J174540.0–290005 was detected during the Swift observing campaign of 2006 and 2007. If the observed outburst duration of 2 weeks is typical for this source, than its outbursts are most easily missed. However, CXOGC J174540.0–290005 was in FOV during the entire Swift campaign of 2006, which encompassed almost daily observations and lasted for 35 weeks. No activity from the source was detected in 33 weeks prior to the outburst that occurred in late October. Therefore, we can assume an upper limit on the duty cycle of $\lesssim 6\%$. This is consistent with the fact that no outburst was detected during the 2007 Swift monitoring observations.
However, since the source was detected with Chandra in 2003 (Muno et al. 2005b), we can also assume that the recurrence time of the system is less than 3 years. From this we can deduct that the duty cycle is likely more than 1%. Using these two bounds combined with an averaged 2–10 keV outburst luminosity of $1 \times 10^{35}$ erg s$^{-1}$, we can put a limit on the time-averaged mass-accretion rate of $3 \times 10^{-13} \, M_{\odot} \, yr^{-1} \leq \langle \dot{M}_{\text{long}} \rangle \leq 1.5 \times 10^{-12} \, M_{\odot} \, yr^{-1}$ for a neutron star compact primary, or $4 \times 10^{-14} \, M_{\odot} \, yr^{-1} \leq \langle \dot{M}_{\text{long}} \rangle \leq 2.1 \times 10^{-13} \, M_{\odot} \, yr^{-1}$ in case it is a black hole.

Following the reported activity of Swift J174540.2–290005 (Kennea et al. 2006c), Wang et al. (2006) performed infrared (IR) observations of the source field on October 30-31, 2006. Whereas no sources within the XRT source position uncertainty showed an expected increase in IR brightness (e.g., Clark et al. 2000; Russell et al. 2006), Wang et al. (2006) concluded that none of them was the counterpart to CXOGC J174540.0–290005. However, we note that the Swift/XRT data shows that at the time of the reported IR observations, the X-ray outburst had already ceased and any correlated IR luminosity might have returned to its pre-outburst level accordingly.

5.3.4 Swift J174553.7–290347

A fourth X-ray transient, which we designate Swift J174553.7–290347, is located $\sim 4.5'$ SW from Sgr A* and was found active for a duration of approximately 2 weeks in 2006 June (see Figure 5.2). The source reached a peak luminosity of $2.0 \times 10^{35}$ erg s$^{-1}$, while the average outburst luminosity was $4.9 \times 10^{34}$ erg s$^{-1}$ (both 2–10 keV). We were able to obtain an improved position of Swift J174553.7–290347 from an archival Chandra observation carried out on 2006 June 17 (see Table 5.2). The source coordinates suggests a possible association with the Chandra detected X-ray point source CXOGC J174553.8–290346 (Muno et al. 2003b), although the offset between the source positions is $\sim 1''$. During the Chandra campaign of the GC (Muno et al. 2003b, 2004, 2005b), CXOGC J174553.8–290346 was detected as a low luminosity X-ray source ($L_X \sim 10^{32}$ erg s$^{-1}$, 2–8 keV) that showed no signs of long- or short-term variability (Muno et al. 2003b).

The spectral shape of CXOGC J174553.8–290346 is not reported in literature, but the reduced Chandra data (both source and background spectra as well as proper response files) from the campaign are made available online (see footnote 7 on page 85). For comparison with the current outburst data, we downloaded the reduced Chandra data and fitted the background corrected spectrum with an absorbed power-law model (after the spectra were grouped to contain at least 20 photons per bin). With the absorption column density fixed at the outburst value of Swift J174553.7–290347, $N_H = 24.4 \times 10^{22}$ cm$^{-2}$, this results in a fit with an unusual steep spectrum; $\Gamma = 5.5 \pm 2.0$. The 2–10 keV unabsorbed X-ray flux for this fit is $(5.0 \pm 4.8) \times 10^{-14}$ erg cm$^{-2}$ s$^{-1}$ and the associated X-ray luminosity would be $3.8 \times 10^{32}$ erg s$^{-1}$.
5 Swift observations of subluminous X-ray transients located near the Galactic centre

Leaving the hydrogen column density as a free parameter results in a fit with $N_H = (11.6 \pm 10.1) \times 10^{22}$ cm$^{-2}$ and $\Gamma = 3.1 \pm 1.7$ and an X-ray luminosity of $\sim 6.8 \times 10^{31}$ erg s$^{-1}$ (2–10 keV). Both the Swift outburst spectrum of Swift J174553.7–290347 and the Chandra spectrum of CXOGC J174553.8–290346 are plotted in combination with the fitted models in Figure 5.3 (the plotted spectral model for CXOGC J174553.8–290346 is for $N_H = 24.4 \times 10^{22}$ cm$^{-2}$).

During the entire 2006–2007 Swift campaign, the new X-ray transient Swift J174553.7–290347 only displayed this 2-week outburst (see Figure 5.2), for which we can infer a 2–10 keV outburst fluence of $8.0 \times 10^{-6}$ erg cm$^{-2}$. The source was not detected during 22 weeks of consecutive observations in 2007, which we can use as a lower limit on the quiescent time scale of this source (which is consistent with the 2006 behaviour). Thus, the duty cycle of Swift J174553.7–290347 is likely less than 8%. The estimate for the long-term average accretion rate of this transient is then $\lesssim 10^{-12}$ M$_\odot$ yr$^{-1}$ for a neutron star X-ray binary or $\lesssim 2 \times 10^{-13}$ M$_\odot$ yr$^{-1}$ in case of an accreting black hole.

5.3.5 Swift J174622.1–290634

Approximately 11′ SW from Sgr A∗, the X-ray transient Swift J174622.1–290634 is active from 2006 mid-May till late-June (see Figure 5.2). We obtained improved coordinates for this new X-ray transient from an archival Chandra observation carried out on 2006 July 7, during which the source was detected (see Table 5.2). This system cannot be identified with any known X-ray source (it was outside FOV of the Chandra monitoring campaign of the GC; Muno et al. 2003b, 2004, 2005b). The average outburst luminosity during the Swift/XRT observations was $1.2 \times 10^{34}$ erg s$^{-1}$ and the observed peak luminosity was $7.0 \times 10^{34}$ erg s$^{-1}$ (both in the 2–10 keV energy band). The 2–10 keV outburst fluence for the 5-week outburst of Swift J174622.1–290634 is $5.0 \times 10^{-6}$ erg cm$^{-2}$.

Swift J174622.1–290634 lies relatively far from Sgr A* and was not always within the FOV, due to varying pointing centres and roll-angles of the Swift/XRT observations. However, the observations were spread such that if the observed outburst duration of 5 weeks is typical for the source, any other outburst occurring during the 2006 monitoring campaign would have been detected by Swift/XRT. During the 6-week interval that the Swift observatory was offline in 2007, Swift J174622.1–290634 could in principle have experienced an accretion outburst of 5 weeks. However, the system was not detected during XMM-Newton observations of the GC performed on 2007 September 6 (i.e., halfway the interval that the Swift observatory was offline), indicating that this is not the case. We therefore assume that the source was in quiescence for the entire 2007 Swift monitoring campaign, which lasted for 31 weeks. The duty cycle of Swift J174622.1–290634 is thus likely less than 14%, which makes
its time-averaged accretion rate \( \lesssim 4 \times 10^{-13} \, \text{M}_\odot \, \text{yr}^{-1} \) for an accreting neutron star or \( \lesssim 6 \times 10^{-14} \, \text{M}_\odot \, \text{yr}^{-1} \) for a black hole X-ray binary.

5.3.6 GRS 1741–2853

The neutron star X-ray transient GRS 1741–2853 (located \( \sim 10' \) NE from Sgr A\(^*\)) was in FOV during most of the Swift monitoring observations (see Figure 5.2). The source has been detected in an active state several times since its initial discovery in 1990 (Sunyaev 1990), displaying typical peak luminosities of a few times \( 10^{36} \, \text{erg s}^{-1} \) (e.g., Muno et al. 2003a; Wijnands et al. 2006a). In 2006 September, GRS 1741–2853 displayed some low level activity, lasting approximately a week (see Figure 5.2, \( \sim 200 \) days after the start of the monitoring observations). The source reached a peak luminosity of \( 8.9 \times 10^{34} \, \text{erg s}^{-1} \) (2–10 keV), which is an order of magnitude lower than its full outburst luminosity, but still about 1000 times higher than its quiescent level (\( \sim 10^{32} \, \text{erg s}^{-1} \) in the 2–8 keV band; Muno et al. 2003a). The fluence of this small outburst is \( 2.6 \times 10^{-6} \, \text{erg cm}^{-2} \) (2–10 keV).

Renewed activity from GRS 1741–2853 was reported in early 2007, as observed with Integral (Kuulkers et al. 2007b), Swift (Wijnands et al. 2007), XMM-Newton (Porquet et al. 2007) and Chandra (Muno et al. 2007b). During its 2007 activity, three type-I X-ray bursts were reported (Wijnands et al. 2007; Porquet et al. 2007) and several of such thermonuclear bursts have been observed in the past (see Muno et al. 2003a, and references therein). GRS 1741–2853 was seen active right from the start of the 2007 Swift/GC observation performed on March 3. It remained as such for approximately 5 weeks, displaying an average 2–10 keV outburst luminosity of \( 1.3 \times 10^{36} \, \text{erg s}^{-1} \), until it returned to quiescence by the beginning of April. During this outburst, Swift/XRT detected a peak luminosity of \( 2.0 \times 10^{36} \, \text{erg s}^{-1} \) (2–10 keV). For the observed outburst duration of 5 weeks, the 2–10 keV fluence of the 2007 outburst is \( 5.3 \times 10^{-4} \, \text{erg cm}^{-2} \).

However, GRS 1741–2853 was already seen active during Integral observations performed on February 15, i.e., 2 weeks before the start of the Swift/GC campaign. Moreover, Wijnands et al. (2007) noted that GRS 1741–2853 is located within the 3’ error circle of an X-ray burst detected by the Burst Alert Telescope (BAT) onboard Swift on 2007 January 22 (Fox et al. 2007). As there were no other sources detected within the BAT error circle, it is likely that GRS 1741–2853 was the origin of this burst, suggesting that the source was already active for over 8 weeks before the start of the Swift/GC campaign. Therefore, the outburst fluence inferred from the Swift/XRT observations should be considered as a lower limit and the true value might be > \( 1.4 \times 10^{-3} \, \text{erg cm}^{-2} \) (2–10 keV), in case the outburst lasted 13 weeks, or longer.
Small outbursts like the one occurring in 2006 with $L_X^{\text{peak}} \sim 10^{35}$ erg s$^{-1}$ and $t_{\text{obs}} = 1$ week, have a negligible effect on the total mass-accretion rate, when compared to longer and brighter outbursts like the one observed in 2007. Therefore, we will not include the 2006 outburst in calculating the mass-accretion rate for GRS 1741–2853 and assume a minimal quiescent time scale of 35 weeks (the span of the 2006 monitoring observations). Adapting a typical outburst duration of 13 weeks (which is likely the minimum duration of the 2007 outburst), we can than place an upper limit on the duty cycle of GRS 1741–2853 of $\lesssim 30\%$. On the other hand, GRS 1741–2853 has been detected at 2–10 keV X-ray luminosities of $\sim 10^{36}$ erg s$^{-1}$ for a total of 5 times since its initial discovery 18 years ago (see Wijnands et al. 2006a, for the long-term lightcurve of this source, showing its various outbursts from 1990 till 2005). Therefore, we assume a lower limit on the duty cycle of $\gtrsim 7\%$. Combining these bounds with a typical 2–10 keV outburst luminosity of $\sim 10^{36}$ erg s$^{-1}$, we estimate a long-term accretion rate of $2 \times 10^{-11} M_\odot$ yr$^{-1} \lesssim \langle \dot{M}_{\text{long}} \rangle \lesssim 8 \times 10^{-11} M_\odot$ yr$^{-1}$ for GRS 1741–2853.

5.3.7 XMM J174457–2850.3

XMM J174457–2850.3 is an X-ray transient located about 13.7′ NE from Sgr A*. The source was discovered in 2001 (Sakano et al. 2005), using XMM-Newton observations, at a peak luminosity of $5 \times 10^{34}$ erg s$^{-1}$, but with a quiescent luminosity of $1.2 \times 10^{32}$ erg s$^{-1}$ (both in the 2–10 keV energy range). Since then, the source has been repeatedly reported active at luminosities ranging from a few times $10^{33}$ erg s$^{-1}$ up to $\sim 10^{36}$ erg s$^{-1}$ (Wijnands et al. 2006a; Muno et al. 2007b).

Due to its large angular separation from Sgr A*, there were only 16 pointings (spaced between 2007 July and November) during the Swift/GC campaign, in which XMM J174457–2850.3 was in FOV (see Figure 5.2). Restricted by a small number of photons, we could not fit to the spectrum of XMM J174457–2850.3. We therefore employed RMFs to convert the observed XRT count rates to fluxes using an absorbed powerlaw model with $N_H = 6.0 \times 10^{22}$ cm$^{-2}$ and $\Gamma = 1.3$ (as found by Sakano et al. 2005). During the first set of 6 observations (performed between 2007 July 5–14 for a total of 6 ks), the source had a 2–10 keV X-ray luminosity of $\sim 1.5 \times 10^{33}$ erg s$^{-1}$. This is at a similar level as was found for the source in 2007 February by Muno et al. (2007b). However, on August 4, the source was clearly detected during a single 1.7 ks observation at $L_X \sim 1.1 \times 10^{34}$ erg s$^{-1}$ (2–10 keV). XMM J174457–2850.3 was again in FOV during a series of 6 Swift monitoring observations carried out between 2007 October 24 and November 2 (which had a total exposure time of $\sim 11.1$ ks). At this time, the source activity was lower again; it displayed a 2–10 keV luminosity of $\sim 1.4 \times 10^{33}$ erg s$^{-1}$.

It is possible that XMM J174457–2850.3 did not reach a luminosity exceeding
5.4 Discussion

We have presented the spectral analysis of seven X-ray transients that were found to be active during a monitoring campaign of the field around Sgr A* using Swift/XRT, carried out in 2006–2007. Two new transients were discovered (Swift J174622.1–290634 and Swift J174553.7–290347) and renewed activity from five known sources was observed (AX J1745.6–2901, CXOGC J174535.5–290124, CXOGC J174540.0–290005, GRS 1741–2853 and XMM J174457–2850.3). Adopting source distances of 8 kpc, we can infer peak luminosities in the range of $\sim 10^{34} - 6 \times 10^{36}$ erg s$^{-1}$ in the 2–10 keV energy band. The two transients AX J1745.6–2901 and GRS 1741–2853 are hybrid systems, that display very-faint outbursts with 2–10 keV peak luminosities of $L_X < 10^{36}$ erg s$^{-1}$, as well as outbursts with luminosities in the range of $10^{34} - 37$ erg s$^{-1}$, which are classified as faint. The other five systems display 2–10 keV peak luminosities of $10^{34} - 36$ erg s$^{-1}$, i.e., in the very-faint regime. We have observed a large variation in spectral properties, outburst luminosities and outburst durations (see Tables 5.3 and 5.4). In that respect, the subluminous transients are not different from the well-known bright systems.
5 Swift observations of subluminous X-ray transients located near the Galactic centre

5.4.1 The nature of the detected transients

AX J1745.6–2901 and GRS 1741–2853 are both known X-ray bursters, which makes it very likely that these are neutron stars in LMXBs, since type-I X-ray bursts have never been detected from high-mass X-ray binaries. For AX J1745.6–2901 an LMXB nature is confirmed by its orbital period of 8.4 h. The nature of the remaining five transients is unknown. However, XMM J174457–2850.3, CXOGC J174535.5–290124 and CXOGC J174540.0–290005, all have been in outburst more than once in the past decade. This likely rules out a white dwarf accretor, since recurrent novae display outburst cycles of decades rather than years. This suggests a neutron star or black hole nature for XMM J174457–2850.3, CXOGC J174535.5–290124 and CXOGC J174540.0–290005. For CXOGC J174540.0–290005, observations reported by Wang et al. (2006) could not detect a near-IR counterpart, while the observations would have detected a main sequence star down to spectral type B5. This suggests that if CXOGC J174540.0–290005 is an X-ray binary, it is likely an LMXB.

The two new transients Swift J174553.7–290347 and Swift J174622.1–290634 were observed at 2–10 keV peak luminosities of \( L_X \sim 2.0 \times 10^{35} \) erg s\(^{-1}\) and \( L_X \sim 7.0 \times 10^{34} \) erg s\(^{-1}\), respectively. Although such luminosities are quite uncommon for white dwarf systems, Mukai et al. (2008) showed a few examples of classical novae that reach peak values of several times \( 10^{34–35} \) erg s\(^{-1}\). Thus, in absence of other outbursts from Swift J174553.7–290347 and Swift J174622.1–290634, we cannot exclude the possibility that these two systems harbour accreting white dwarfs.

5.4.2 Subluminous X-ray transients in quiescence

The quiescent luminosity of X-ray transients sometimes holds clues to the nature of the system. The ASCA burster AX J1745.6–2901 is very likely associated with CXOGC J174535.6–290133, which was detected several times with Chandra at a level of a few times \( 10^{32} \) erg s\(^{-1}\) (see Sect. 5.3.1). This is consistent with the neutron star nature of AX J1745.6–2901, since black hole systems with an orbital period of \( \sim 8 \) h are significantly fainter (e.g., Narayan et al. 1997; Menou et al. 1999; Lasota 2007). GRS 1741–2853 is also a confirmed neutron star system and displays a similar quiescent level of \( \sim 10^{32} \) erg s\(^{-1}\) (2–8 keV, Mun et al. 2003a).

The possible quiescent counterpart of the new subluminous X-ray transient Swift J174553.7–290347, the Chandra-detected X-ray source CXOGC J174553.8–290346, displays a 2–10 keV X-ray luminosity of \( \sim 7 \times 10^{31} – 4 \times 10^{32} \) erg s\(^{-1}\), depending on the assumed spectral model (see Sect. 5.3.4). The quiescent luminosity of XMM J174457–2850.3 is also in this regime; \( \sim 10^{32} \) erg s\(^{-1}\) (2–10 keV; Sakano et al. 2005). If Swift J174553.7–290347 and XMM J174457–2850.3 are X-ray binaries, their quiescent luminosities are relatively high and might point towards a neutron star nature.
5.4 Discussion

(e.g., Lasota 2007), although the orbital period of both these systems is unknown. We note that the absorption towards our transients is very high (> 6 × 10^{22} \text{ cm}^{-2}). Therefore, any thermal emission from the neutron star surface cannot be observed and we can only detect contributions from a powerlaw component, which is frequently observed for neutron stars at similarly low quiescent luminosities (e.g., Jonker 2008).

CXOGC J174535.5–290124 and CXOGC J174540.0–290005, two other transients, were not detected in quiescence, but have upper limits on their luminosities of < 9 × 10^{30} \text{ erg s}^{-1} and < 4 × 10^{31} \text{ erg s}^{-1}, respectively (2–8 keV; Muno et al. 2005b). Such low quiescent luminosities are more common for black hole X-ray binaries than for neutron star systems (e.g., Garcia et al. 2001; Lasota 2007, but see Jonker et al. 2006, 2007).

5.4.3 The outbursts of subluminous X-ray transients

The disc instability model (e.g., King & Ritter 1998; Dubus et al. 1999; Lasota 2001) provides a framework to describe the outburst cycles of transient LMXBs. However, it is unclear why some X-ray transients, such as the ones discussed here, undergo outbursts with very low peak luminosities. AX J1745.6–2901 has a known orbital period of 8.4 h, which allows for a maximum luminosity of ~ 2 × 10^{38} \text{ erg s}^{-1} (for a hydrogen-dominated disc and a neutron star mass of 1.4 M_{\odot}; Lasota 2007). Yet, its observed peak luminosity is over an order of magnitude lower (see Table 5.3). Since AX J1745.6–2901 displays eclipses, we must look at the system at high inclination. For several eclipsing X-ray binaries observations suggest that these are intrinsically bright but appear faint because the bright centre of the system is blocked by the outer edge of the disc and the corona (e.g., Parmar et al. 2000; Kallman et al. 2003; Muno et al. 2005a). This may also be the case for AX J1745.6–2901, for which Maeda et al. (1996) derived an inclination angle of i ~ 70^\circ. To include inclination effects, the observed X-ray luminosity should be corrected by a factor \xi_p, which relates to the inclination, i, as \xi_p^{-1} = 2|\cos i| (Fujimoto 1988; Lapidus & Sunyaev 1985). In 2007, AX J1745.6–2901 displayed a 2–10 keV peak luminosity of 6.1 × 10^{36} \text{ erg s}^{-1}, which corrects to 9.2 × 10^{36} \text{ erg s}^{-1} for the suggested inclination of i ~ 70^\circ (\xi_p ~ 1.5).

It is thus conceivable that AX J1745.6–2901 is a bright X-ray transient that is obscured due to line of sight effects, although it would still seem to be at the lower end of the luminosity range for bright systems (peak luminosities of ~ 10^{37–39} \text{ erg s}^{-1} in the 2–10 keV energy band). For comparison, the quasi-persistent neutron star system MXB 1659–29 has an orbital period of 7.1 h (Cominsky et al. 1983), which is close that of AX J1745.6–2901. However, MXB 1659–29 displays an average 2–10 keV outburst luminosity of 7 × 10^{36} (D/10 \text{kpc}) \text{ erg s}^{-1} (Oosterbroek et al. 2001; Sidoli et al. 2001b), which is about a factor of 4 higher than the average 2–10 keV outburst luminosity observed for AX J1745.6–2901 in 2007; 1.6 × 10^{36} \text{ erg s}^{-1}. Possibly, the
inclusion of AX J1745.6–2901 is somewhat higher than the $i \sim 70^\circ$ suggested by Maeda et al. (1996). AX J1745.6–2901 might have a subluminous appearance due to line of sight effects, but it is important to note that statistical arguments show that such effects cannot account for the entire population of subluminous X-ray transients, and that most systems must have low intrinsic luminosities (see the discussion of Wijnands et al. 2006a).

Although taking into account inclination effects potentially pushes AX J1745.6–2901 into the regime of bright X-ray transients, this does not provide an explanation for the peculiar outburst behaviour of the source. As discussed in Sect. 5.3.1, the system was likely in quiescence for several years before it was seen active in 2006 for more than 4 months. At that time, the source reached a peak luminosity of $9.2 \times 10^{35}$ erg s$^{-1}$, which would classify the system as very-faint. However, after several months of quiescence (see Figure 5.2), the source reappeared displaying a peak luminosity of $6.1 \times 10^{36}$ erg s$^{-1}$ (i.e., in the faint regime) and remained active for over 1.5 years (see Sect. 5.3.1). Thus, the outburst observed in 2006 was subluminous by about a factor of 6 compared to the 2007 outburst, yet the system maintained this low luminosity for months. It is unclear if this behaviour can be explained in terms of a disc instability model. In 1993 and 1994, different outburst luminosities of $2 \times 10^{35}$ erg s$^{-1}$ and $9 \times 10^{35}$ erg s$^{-1}$ were reported for AX J1745.6–2901 (3–10 keV, Maeda et al. 1996). This is on the same time scale as the discussed Swift detections, suggesting that the behaviour observed in 2006 and 2007 could be typical for the source.

GRS 1741–2853 also displayed two separate outbursts with very different characteristics in terms of peak luminosity and outburst duration during the Swift/XRT monitoring observations. A short, $\sim 1$–week outburst was detected in 2006, which had a 2–10 keV peak luminosity of $9.2 \times 10^{34}$ erg s$^{-1}$. A few months later, the source exhibited a much longer ($\geq 13$ weeks) outburst, that reached a peak luminosity of $2.0 \times 10^{36}$ erg s$^{-1}$ (2–10 keV). Possibly, the short 2006 outburst of GRS 1741–2853 was an X-ray precursor for the 2007 outburst. Such behaviour is observed for several bright X-ray transients (both neutron star and black hole systems, see Chen et al. 1997, and references therein). Both Swift J174553.7–290347 and CXOGC J174540.0–290005 displayed short, $\sim 2$–week outbursts that had an average luminosity of a few times $10^{34}$ erg s$^{-1}$. This kind of activity resembles the small accretion outburst of GRS 1741–2853 in 2006 (see Figure 5.2), but for these two systems no longer outbursts have been observed. XMM J17445–2850.3 seems to undergo X-ray activity at different luminosity levels as well (see Sect. 5.3.7). It is unclear what causes the varying accretion luminosities. However, this phenomenon is also observed for bright X-ray transients and is thus not restricted to the subluminous systems discussed here.
Current disc instability models do not provide an obvious explanation for accretion outbursts that last several years, rather than the usual weeks to months, such as observed for AX J1745.6–2901. A few bright systems are known to undergo quasi-persistent outbursts (see e.g., Wijnands 2004). There are also two X-ray transients that exhibit prolonged outbursts at low luminosities. XMMU J174716.1–281048 has likely been continuously active since its initial discovery in 2003, displaying a typical 2–10 keV luminosity of a few times $10^{34}$ erg s$^{-1}$ (e.g., Del Santo et al. 2007b; Degeenaar & Wijnands 2007). Furthermore, AX J1754.2–2754 recently made a transition to quiescence (Bassa et al. 2008), after exhibiting an accretion outburst with a 2–10 keV luminosity of several times $10^{34}$–$10^{35}$ erg s$^{-1}$, which likely lasted for 7–8 years (Sakano et al. 2002; Del Santo et al. 2007a; Chelovekov & Grebenev 2007). This source was again found active in July 2008 (Jonker & Keek 2008). The detection of type-I X-ray bursts identifies both these systems as neutron star LMXBs, just like AX J1745.6–2901.

### 5.4.4 X-ray bursts from subluminous X-ray transients

The properties of type-I X-ray bursts are set by the conditions in the flash layer such as the temperature, thickness, hydrogen abundance and the fraction of carbon-nitrogen-oxygen (CNO) elements in the layer (e.g., Fujimoto et al. 1981; Bildsten 1998; Peng et al. 2007). These conditions can vary drastically as the mass-accretion rate onto the neutron star ($\dot{M}$) varies, which results in flashes with different characteristics for different $\dot{M}$ regimes (e.g., Fujimoto et al. 1981; Peng et al. 2007; Cooper & Narayan 2007).

The *Swift*/XRT monitoring observations of 2006 caught two type-I X-ray bursts from AX J1745.6–2901 (see Sect. 5.3.1). The average 2–10 keV luminosity of the 2006 outburst was $3.9 \times 10^{35}$ erg s$^{-1}$, from which we can estimate an instantaneous mass accretion rate onto the neutron star of $\sim 1 \times 10^{-10}$ M$_{\odot}$ yr$^{-1}$. If we include a correction factor to account for inclination effects, as discussed in Sect. 5.4.3, this value increases to $\sim 1.5 \times 10^{-10}$ M$_{\odot}$ yr$^{-1}$. The bursts had a duration of 50–60 seconds (see Figure 5.4), which suggests triggering in a mixed hydrogen/helium environment. This is in line with the classical predictions for the estimated mass-accretion rate (e.g., Fujimoto et al. 1981).

We discussed in Sect. 5.3.1, that the type-I X-ray bursts observed from AX J1745.6–2901 have 0.01–100 keV peak luminosities of $\sim 10^{38}$ erg s$^{-1}$, close to the Eddington limit of a neutron star. These peak values should also be corrected for the inclination effects discussed in Sect. 5.4.3. However, the X-ray burst (originating from the neutron star surface) and the outburst emission (emerging from the accretion disc) are attributed to geometrically different regions and may therefore have different degrees of isotropy (Fujimoto 1988; Lapidus & Sunyaev 1985). Although, the
5 Swift observations of subluminous X-ray transients located near the Galactic centre

X-ray burst emission will be partly intercepted and re-radiated by the accretion disc, it was shown that the degree of anisotropy is less than for the emission coming from the accretion disc (Fujimoto 1988; Lapidus & Sunyaev 1985). Inclination effects are expected to reduce the X-ray burst emission by a factor $\xi_b^{-1} = 0.5 + |\cos i|$ (Fujimoto 1988; Lapidus & Sunyaev 1985). For the suggested inclination of $i = 70^\circ$ (Maeda et al. 1996), we thus obtain a correction factor of $\xi_b = 1.2$. This implies peak luminosities for the type-I X-ray bursts observed from AX J1745.6–2901 on 2006 June 3 and 14 of $(1.2 - 1.6) \times 10^{38}$ erg s$^{-1}$ and $(0.62 - 1.3) \times 10^{38}$ erg s$^{-1}$ (0.01–100 keV), respectively. This is below, but close, to the Eddington luminosity for a neutron star ($2.0 \times 10^{38}$ erg s$^{-1}$ for a hydrogen-rich and $3.8 \times 10^{38}$ erg s$^{-1}$ for a hydrogen-poor photosphere; e.g., Kuulkers et al. 2003).

5.4.5 Long-term average accretion rates

Presuming that the detected transients are accreting systems, we attempted to estimate their long-term time-averaged accretion rates using the method and described in Sect. 5.2.2. We explored the scenarios of both neutron star and black hole accretors (except for AX J1745.6–2901 and GRS 1741–2853, since these are confirmed neutron star systems), which resulted in the estimated long-term mass-accretion rates listed in Table 5.4. The two confirmed neutron star systems, AX J1745.6–2901 and GRS 1741–2853 have the highest estimated accretion rates of the seven discussed transients ($\sim 10^{-11} - 10^{-10}$ M$_\odot$ yr$^{-1}$). This arises from the fact that GRS 1741–2853 is active quite regularly and AX J1745.6–2901 can be in outburst for a very long time (over 1.5 years). The regime estimated for these two sources can be well explained within current LMXB evolution models. The same is likely true for XMM J174457–2850.3, which was active several times since its discovery in 2001 and has an estimated long-term mass-accretion rate of $\gtrsim 10^{-11}$ M$_\odot$ yr$^{-1}$.

The estimates for the remaining four systems, CXOGC J174535.5–290124, CXOGC J174540.0–290005, Swift J174553.7–290347 and Swift J174622.1–290634 are much lower; $\lesssim 10^{-12}$ M$_\odot$ yr$^{-1}$ for accreting neutron stars and even an order of magnitude lower for black hole X-ray binaries, $\lesssim 10^{-13}$ M$_\odot$ yr$^{-1}$ (see Table 5.4). Comparing our results with a theoretical toy-model of King & Wijnands (2006), who explored the mechanism of Roche-lobe overflow at low accretion rates, suggests that if these transients are LMXBs, their low time-averaged mass-accretion rates might pose difficulties explaining their existence, without invoking exotic scenarios such as accretion from a planetary donor or an intermediate mass black hole as the accreting primary (King & Wijnands 2006). These are thus interesting systems to track and monitor in the future.

Apart from evolutionary scenarios and line-of-sight effects, there other possible explanations for the subluminous X-ray appearance of these transients. For example,
in particular for the systems containing a black hole, the liberated accretion power may not be primarily dissipated as X-rays but rather via radiative inefficient flows (e.g., Blandford & Begelman 1999; Fender et al. 2003; Narayan & McClintock 2008). In neutron star systems the propeller mechanism can possibly operate, so that only a small fraction of the mass transferred from the donor can be accreted onto the neutron star (e.g., Illarionov & Sunyaev 1975; Alpar 2001; Romanova et al. 2005).

AX J1745.6–2901, GRS 1741–2853 and XMM J174457–2850.3 are three examples that illustrate that X-ray transients can display different behaviour in terms of peak luminosity, outburst duration and recurrence time from year to year. It is currently not understood whether these variations should be interpreted as, e.g., being due to changes in the mass-transfer rate from the donor star or as the result of instabilities in the accretion disc. Such issues need to be resolved before we can fully comprehend the nature of subluminous X-ray transients.

</table>

Note.– The outburst fluences are for the 2–10 keV energy band and were calculated by multiplying the mean unabsorbed outburst flux by the outburst duration. $\langle \dot{M}\rangle_{\text{NS}}$ and $\langle \dot{M}\rangle_{\text{BH}}$ are the estimated long-term averaged accretion rates for a neutron star with $M = 1.4$ M$_{\odot}$ and $R = 10$ km and a black hole with $M = 10$ M$_{\odot}$ and $R = 30$ km, respectively. AX J1745.6--2901 and GRS 1741--2853 both display type-I X-ray bursts and are thus confirmed neutron star systems.
