MXenes are a new family of 2D carbides or nitrides that have attracted attention due to their layered structure, tunable surface groups and high electrical conductivity. Here, we report for the first time that the Ti₂CTₓ MXene catalyses the selective oxidative dehydrogenation of n-butane to butenes and 1,3-butadiene. This catalyst showed higher intrinsic activity compared to a commercial TiC and TiO₂ samples in terms of C₄ olefin formation rate. We propose that the stabilisation of structural vacancies and the change in composition (from a carbide to a mixed phase oxide) in the MXene causes its higher catalytic activity. These vacancies can lead to a higher concentration of unpaired electrons in the MXene-derived material, enhancing its nucleophilic properties and favouring the production of olefins.

**Introduction**

Lower olefins (C₂⁻⁴⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻Vin⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻⁻
of 2D carbides or nitrides where M represents an early transition metal, X is carbon and/or nitrogen, T represents surface terminations such as fluorine, hydroxyl and/or oxygen atoms, and n = 1, 2 or 3.

MXenes (for example Ti$_2$CT$_x$) are generally obtained from the chemical etching of the respective MAX phases (in this example, Ti$_2$AlC). Inheriting their carbon vacancy sites, MXenes (for example Ti$_2$CT$_x$) are obtained from the chemical etching of the respective MAX phases. Previous work found the presence of these vacancies in Ti$_2$C$_x$T$_y$ and Ti$_2$CT$_x$ MXenes by means of density-functional theory (DFT) calculations, electron paramagnetic resonance (EPR) and high-angle annular dark field combined with scanning transmission electron microscopy (HAADF-STEM).

Despite the catalytic potential of structural vacancies in MXenes and the increasing interest of these in electro- and photo-catalytic applications, the use of MXene vacancy sites in thermal heterogeneous catalysis remains unexplored. Here we show that vacancy sites in MXenes can affect the catalytic performance. We tested a Ti$_2$CT$_x$ MXene-derived catalyst during n-butane oxidative dehydrogenation (Scheme 1), which is believed to proceed via the Mars-van Krevelen mechanism.
formation rate (31 mmol C\textsubscript{2}\·Ti atoms\textsuperscript{-1}\cdot min\textsuperscript{-1}) than TiC (8.6 mmol C\textsubscript{2}\·Ti atoms\textsuperscript{-1}\cdot min\textsuperscript{-1}).

The characterisation of the as-prepared and spent catalysts gave more insights into the working of these catalysts. XPS (Figure S5) and Raman (Figure S6) show that the as-prepared Ti\textsubscript{3}CT\textsubscript{x} MXene contains TiO\textsubscript{2} (anatase and rutile) on its surface, due to its partial oxidation during synthesis.\textsuperscript{[27–30]} We confirmed the presence of defects (i.e. unpaired electrons) in the Ti\textsubscript{3}CT\textsubscript{x} structure using X-band electron paramagnetic resonance (EPR). The intense featureless signal at \(g_{\text{xx}} = g_{\text{yy}} = g_{\text{zz}} = 1.9875\) (Figure 3a) corresponds to Ti\textsuperscript{3+} regular lattice positions of the TiO\textsubscript{2} anatase structure and/or Ti\textsuperscript{3+} sites in a defective titanium carbide structure.\textsuperscript{[15,37]} This reveals that the MXene contains a defective TiO\textsubscript{2}/Ti\textsubscript{3}CT\textsubscript{x} structure, with oxygen and/or carbon vacancies that leave behind electrons located at Ti\textsuperscript{3+} positions. We believe that the MXene lattice defects promote the presence of electron-rich oxygen species that enhance the selectivity to butenes during butane ODH (previously, we showed that a similar assumption holds for the Ti\textsubscript{3}AlC\textsubscript{x} MAX phase\textsuperscript{[36]})

Characterisation of the spent Ti\textsubscript{3}CT\textsubscript{x} and TiC materials indicate that both carbides completely oxidise to a mixture of anatase and rutile TiO\textsubscript{2} under reaction conditions (see XRD in Figure S7, XPS in Figure S8 and Raman in Figures S6 and S9a).\textsuperscript{[18,39]} Nevertheless, the spent MXene maintains its layered structure and porosity, with only a slight decrease in the BET surface area from 33 to 26 m\textsuperscript{2}·g\textsuperscript{-1} (see Figure S1b).

The EPR spectrum of the spent Ti\textsubscript{3}CT\textsubscript{x} catalyst shows a major featureless signal at \(g_{\text{xx}} = g_{\text{yy}} = g_{\text{zz}} = 2.0020\) (Figure 3b), which can be attributed to oxygen centred unpaired electrons.\textsuperscript{[15,40]} The spectrum shows other minor resonances, of which the small peaks located at \(g < 2\) are tentatively assigned to Ti\textsuperscript{3+} centred unpaired electrons.\textsuperscript{[41]} These results confirm that the spent MXene retains its structural vacancies.

The EPR spectrum of the spent TiC sample shows a complicated mixture of various unpaired electrons, making the definite assignment of the various components difficult (Figure S9b). The signals observed at \(g > 3.5\) (<170 mT) are indicative of inter- and intramolecular spin-spin interactions, leading to formally forbidden transitions in the X-band EPR measurement. These, combined with the observed multiple species, indicate that the unpaired electron density in spent TiC is high and distributed on different sites.

Despite their similar composition, Ti\textsubscript{3}CT\textsubscript{x} and commercial TiC present different electronic properties that result in different butane ODH catalytic behaviour. The spent Ti\textsubscript{3}CT\textsubscript{x} contains unpaired electrons mainly centred on oxygen vacancies, while the spent TiC showed a broader distribution of unpaired electrons. The electronic properties of the materials influence the type of oxygen species generated during ODH. We hypothesise that the TiC catalyst stabilises electrophilic oxygen species under reaction, favouring the over-oxidation of butane to CO and CO\textsubscript{2}.

As both Ti\textsubscript{3}CT\textsubscript{x} and commercial TiC materials are oxidised to titanium oxide during the reaction, we also tested TiO\textsubscript{2} (anatase, rutile and a mixture of both phases) under the same conditions. Commercial anatase TiO\textsubscript{2} and thermally treated TiO\textsubscript{2} were used, and XRD and Raman spectroscopy (Figure S10) confirmed their composition. Pure anatase and pure rutile phases were inactive during n-butane ODH (Figure S11). This can be ascribed to the absence of defects (i.e. unpaired
electrons) in their structure, as the EPR spectrum of anatase TiO$_2$ does not show any distinct paramagnetic signal (Figure S12a). Thus, despite their high surface area, pure TiO$_2$ phases are not active in the reaction. The TiO$_2$ (A + R) catalyst was the only oxide that showed high activity, with comparable conversion values to the Ti$_2$CT$_x$ catalyst (Figure S11). However, its intrinsic activity in terms of C$_2$ olefin formation rate was much lower compared to the Ti$_2$CT$_x$ MXene (see Figure 2). This indicates that the sites on the Ti$_2$CT$_x$ MXene-based catalyst are intrinsically more active despite the much lower surface Ti content (0.6%) compared to TiO$_2$ (A + R) (23.4% Ti content).

The very weak signal observed in EPR for TiO$_2$ (A + R) (Figure S12b) indicates only a few defects (i.e. oxygen vacancies). Thus, the intrinsic activity of this material is lower compared to the vacancy-rich MXene-based catalyst. Padayachee et al. previously reported the enhanced performance of a mixture of anatase and rutile TiO$_2$ phases compared to the pure individual phases during n-octane ODH.\(^\text{[5]}\) The authors ascribed the catalytic activity to the disorder of the TiO$_2$ lattice at the anatase–rutile junction. This is in line with our results, as only the local disorder created in the TiO$_2$ (A + R) sample can convert butane into C$_2$ olefins. Nevertheless, the apparent lower density of unpaired electrons in this sample results in a lower C$_2$ formation rate compared to the MXene-based catalyst.

Overall, we show here the important role of structural defects (i.e. vacancies) in the electronic and catalytic properties of a MXene-derived catalyst. We believe that these properties can be explored in other type of heterogeneous catalytic applications, as already seen in dry reforming, dehydrogenation and hydrolysis reactions.\(^\text{[42-45]}\) In addition, structural vacancies in MXenes are promising host sites for guest metal atoms, leading to hetero-MXenes.\(^\text{[46]}\) The controlled doping of transition metals in the MXene structure broadens the scope of bifunctional catalytic systems. For example, vanadium and nitrogen groups were evenly incorporated between the Ti$_2$C$_2$T$_x$ MXene interlayers with C–V–O sites formed at the Ti vacancies.\(^\text{[47]}\) Recently, Song et al. used Ti vacancy defects as anchoring sites for cobalt atoms, leading to a single atom Co@Ti$_2$N material.\(^\text{[48]}\)

Conclusions

This study shows the potential of structural vacancies in MXenes for heterogeneous catalysis applications. We tested a series of Ti-based materials (Ti$_2$CT$_x$ MXene, commercial TiC and TiO$_2$) in n-butane oxidative dehydrogenation (ODH). The Ti$_2$CT$_x$ MXene was the most active catalyst in terms of C$_2$ olefin formation rate. We attribute this to its final composition, a mixture of anatase and rutile TiO$_2$, and to its ability to stabilise structural defects. This leads to a high concentration of unpaired electrons, which favours the nucleophilic character of the catalyst surface and thus the production of olefins. A commercial TiC of similar composition was less active and selective than the MXene-based catalyst, most likely due to its electronic properties. Although the local environment of a TiO$_2$ (A + R) catalyst increased its activity compared to pure anatase or rutile phases, its C$_2$ formation rate was significantly lower compared to the MXene. We believe this is because of the low content of unpaired electrons in the (A + R) catalyst structure. Thus, the final composition of the 2D MXene-derived catalyst and the stabilisation of its vacancies, combined with its electronic properties, make MXenes promising active and stable catalysts in high-temperature reactions such as n-butane ODH.

Experimental Section

Materials and instrumentation

Powder X-Ray diffraction (XRD) measurements were carried out on a MiniFlex II diffractometer using Cu Kα radiation. The XRD patterns were recorded at an angle (2θ) range of 5–90° with a turning speed of 2.5°·min$^{-1}$. N$_2$ adsorption-desorption isotherms at 77 K were measured on a Thermo Scientific Surfer instrument. The samples were pre-treated under vacuum at 200 °C for 16 h. X-Ray Photoelectron Spectroscopy (XPS) spectra were measured in a K-Alpha spectrometer from Thermo-Scientific. The binding energies (BE) were referenced to the C 1s line at 284.6 eV, with an accuracy of ±0.2 eV. The experimental details can be found in Ronda-Lloret et al.\(^\text{[49]}\)

Scanning electron microscopy (SEM) micrographs were obtained on a scanning electron microscope Hitachi S3000 N. Confocal Raman spectra were recorded at 532 nm using a Renishaw (Wottonunder-Edge, United Kingdom) InVia Reflex Raman microscope with a 532 nm frequency-doubled Nd:YAG excitation source in combination with a 1800 lines mm$^{-1}$ grating, and a Peltier-cooled CCD detector (203 K). The 521 cm$^{-1}$ Raman shift of a silicon standard was used to verify the spectral calibration of the system.\(^\text{[50]}\) X-band EPR spectra were acquired in the solid phase at 10 K on a Bruker EMX X-band spectrometer, equipped with an ER 4112HV-CF100 cryostat, and further analysed and simulated using EasySpin.\(^\text{[51]}\)

Procedure for catalyst synthesis

All chemicals were obtained from commercial sources and were used as received. The synthesis of the Ti$_2$AlC MAX phase has been described previously.\(^\text{[52,53]}\) The Ti$_2$CT$_x$ MXene was prepared from the chemical etching of Ti$_2$AlC. In a typical procedure, 2 g of Ti$_2$AlC were mixed with 1.3 g of LiF previously dissolved in 100 mL of 12 M HCl. The mixture was stirred under heating at 70 °C for 24 h. The resulting powder was repeatedly centrifuged and washed with deionized water until the pH of the supernatant was neutral. The obtained solid was dried under vacuum at 30°C for 12 h. Commercial TiC was purchased from WWR International B.V. Commercial TiO$_2$ anatase (Hombikat M311) was used as control sample. Rutile TiO$_2$ was obtained from the thermal treatment of anatase TiO$_2$ at 1000 °C under air for 1 h. The thermal treatment of anatase TiO$_2$ at 800 °C produced a mixture of anatase and rutile (A + R).

Procedure for catalytic testing

The catalysts were tested in the n-butane oxidative dehydrogenation (ODH) reaction using an automated six-flow parallel reactor system, which contains six quartz reactors. A total of 300 mg of catalyst was placed in the reactor in the form of pellets (1–
Conversion, selectivity and carbon balance values were calculated using Equations (1–3). The rate of total butenes formation (r(B)), Eq. (4) was calculated taking into account the amount of surface Ti available on each catalyst (based on the XPS results, Table S2) and the molecular weight of each catalyst (Mw).

\[
\text{Conversion of butane (\%)} = \frac{[\text{Butane}]_{in} - [\text{Butane}]_{out}}{[\text{Butane}]_{in}} \times 100
\]
