ABSTRACT

Aims This study was designed to investigate the counterbalancing influence of genetic variation in the promoter of the gene encoding P300/CBP associated factor (PCAF), a lysine acetyltransferase (KAT), on coronary heart disease (CHD) and mortality.

Methods and results The association of genetic variation in the PCAF-gene with CHD, restenosis and mortality was investigated in three large cohorts. The results were combined to examine overall effects on CHD mortality and on restenosis risk. Compared with the homozygous −2481G allele in the PCAF promoter, a significant reduction in CHD mortality risk with the homozygous −2481C PCAF promoter allele was observed. A combined risk reduction for CHD death for the three studies was 21% (15–26%, p=8.1×10⁻⁴). In elderly patients (>58 years) the effects were stronger. Furthermore, this PCAF allele was significantly associated with all-cause mortality (p=0.001).

Functional analysis showed that nuclear factors interact in vitro with the oligonucleotides encompassing the −2481G/C polymorphism and that this interaction might be influenced by this polymorphism in the PCAF promoter. Moreover, modulation of PCAF-gene expression was detectable upon cuff-placement in an animal model of reactive stenosis.

Conclusion We showed in three large prospective studies that the −2481C allele in the PCAF promoter is associated with a significant survival advantage in elderly patients. Our observations promote the concept that epigenetic processes are under genetic control and that, other than environment, variation in genes encoding KATs may also determine susceptibility to CHD outcomes and mortality.

Investigations into the pathogenetic mechanisms of human complex disease, such as cardiovascular disease and cancer, may lead to better risk prediction, treatment and new targets for future therapy. Cell proliferation regulatory pathways and pro-inflammatory transcription factors, such as nuclear factor kappa B (NFκB), have been associated with the progression of these diseases.1 In the past decade, research into cardiovascular diseases, such as atherosclerosis and restenosis, has been focused on the identification of genetic factors that determine disease risk. Several genes involved in inflammation and cell proliferation appeared to be common denominators of these diseases.2–4 It has become clear, however, that part of the gene–environment interactions relevant for complex diseases is regulated by epigenetic mechanisms such as histone acetylation and DNA methylation.5 Epigenetic processes modulate gene expression patterns without modifying the actual DNA sequence and have profound effects on the cellular repertoire of expressed genes.6 Evidence is growing that epigenetic mechanisms also regulate the expression of genes in the inflammatory and cell proliferation pathways7,8 and may therefore also play a role in cardiovascular disease.9–11

A major influence on gene expression is attributed to the counterbalancing action of lysine acetyltransferases (KAT) and lysine deacetylases (KDAC).12 KAT acetylate histones by transfer of an acetyl group to the -portion of lysine residues, which results in an open modification of chromatin structure and in accessibility of DNA to transcription factors and recruitment of the basal transcription initiation machinery. Conversely, gene repression is mediated via KDAC, which remove acetyl groups and counteract the activity of KAT resulting in a closed chromatin structure. Thus far, the main focus has been to investigate the environmental influence on epigenetic processes. Research in this field has shown that epigenetic differences arise during the lifetime of monozygotic twins.6 Furthermore, oxidative stress has been shown to influence the balance between KAT and KDAC in favour of KAT, leading to an increase in inflammation.13 Notably, genetic variations in the genes encoding KAT and KDAC, which affect the activities of the enzymes they encode, have a bearing on the global and gene-specific levels of histone acetylation. As such, these genetic variations in the genes encoding KAT and KDAC could
also be important determinants contributing to susceptibility to major human diseases.

P500/CBP-associated factor (PCAF) is a transcriptional co-activator with intrinsic KAT activity. Besides its role in lysine acetylation of histones at the site of NFκB-regulated genes and the resultant inflammatory gene activation,14 15 PCAF is also found to act as a factor acetyltransferase that acetylates non-histone proteins, including several tumour-suppressor proteins, such as p5316 17 and the phosphatase and tensin homologue.18 Because PCAF is involved in proliferation and inflammation, common denominators of the major diseases determining human mortality, with clear evidence for inflammatory factors predicting incident cardiovascular disease events,19 20 incident cancer,21 and mortality, we hypothesised that the PCAF gene could be of major importance in the development of cardiovascular disease and cancer and death from such diseases.

We investigated the impact of genetic variation in the promoter region of the PCAF gene on all-cause mortality and mortality due to coronary heart disease (CHD) and cancer in the PROSPER-study, a randomised controlled trial in which 5804 elderly patients (aged 70–82 years) at risk of vascular disease were randomly assigned to pravastatin or placebo.22 In order to validate the observed effects and to be able to extrapolate our findings to a younger population, we investigated the PCAF gene in the WOSCOPS study, a randomised controlled trial similar to the FRESOR study, designed to determine the effect of pravastatin in middle-aged men with hypercholesterolaemia without a history of cardiovascular disease. Finally, in order to test further the validity of results in the two statin trials, and to gain insights into the mode of action, we investigated these variants in another study that included 3104 patients undergoing percutaneous coronary intervention (PCI).23 The primary endpoint in that study was clinical restenosis, a process that is known to be mainly determined by inflammation and proliferation.2

All participants in the three study groups were analysed for two single nucleotide polymorphisms (SNP) in the promoter region of the PCAF gene. Of these polymorphisms, the −2481G/C SNP was found to be significantly associated with CHD mortality in elderly patients in PROSPER and WOSCOPS and, in addition, with a differential risk of restenosis in the GENDER study.

METHODS

Study design and follow-up of the PROSPER study

The protocol of PROSPER has been described elsewhere.24 PROSPER is a prospective multicentre randomised placebo controlled trial to assess whether treatment with pravastatin diminishes the risk of major vascular events in elderly individuals. Between December 1997 and May 1999, we screened and enrolled subjects in Scotland (Glasgow), Ireland (Cork), and The Netherlands (Leiden). Men and women aged 70–82 years were recruited if they had pre-existing vascular disease or an increased risk of such disease because of smoking, hypertension, or diabetes. A total number of 5804 subjects was randomly assigned to pravastatin or placebo. In this genetic substudy, we evaluated the predefined endpoints all-cause mortality and mortality due to vascular events and cancer. Mean follow-up was 3.2 years (range 2.8–4.0) and 604 (10.4%) patients died during the study.25 Of these patients, 292 (48%) died from vascular disease and 206 (31%) from cancer.

Study design and follow-up of the WOSCOPS study

The WOSCOPS study (the West of Scotland Coronary Prevention Study), a primary prevention trial, included 6595 men, aged between 45 and 64 years, who had low-density lipoprotein cholesterol levels between 174 and 252 mg/dl (4.5 and 6.0 mmol/l), who had no history of myocardial infarction, but were considered to be at enhanced risk of developing CHD.25 The first patient was enrolled on 1 February 1989, and the study ended on 15 May 1995. The mean follow-up duration was 4.9 years. All participants were randomly assigned to receive 40 mg of pravastatin or placebo daily.

The present genetic study was performed in a previously described nested case–control cohort.26 In brief, the prospective nested case–control study included all of the 580 on-trial CHD events (death from CHD, non-fatal myocardial infarction, or revascularisation procedures) from the WOSCPoS cohort as case subjects and 1160 control subjects matched to case subjects by age and smoking. In the present genetic study we used death from CHD as our primary endpoint.

Study design and follow-up of the GENDER study

The present study sample has been described previously.23 In brief, the GENETIC Determinants of Restenosis project (GENDER) was a multicentre follow-up study designed to study the association between various gene polymorphisms and clinical restenosis. Patients eligible for inclusion in the GENDER study were treated successfully for stable angina, non-ST-elevation acute coronary syndromes or silent ischaemia by PCI in four out of 13 referral centres for interventional cardiology in The Netherlands. Patients treated for acute ST-elevation myocardial infarction were excluded. Experienced operators, using a radial or femoral approach, performed standard angioscopy and stent placement. During the study, no drug-eluting stents were used. Follow-up lasted for at least 9 months, except when a coronary event occurred. Clinical restenosis, defined as target vessel revascularisation (TVR), either by PCI or coronary artery bypass grafting, was the primary endpoint. Median follow-up duration was 9.6 months (IQR 3.9) and 304 (9.8%) patients underwent TVR during follow-up. A prespecified subpopulation of 478 patients was scheduled for re-angiography at 6 months, according to standard procedures, as described previously.27 Identical projections were used before, during and 6 months after the PCI for all assessed angiograms. Quantitative computer analyses were independently performed by Heartcore (Leiden, The Netherlands).

For all three studies, all endpoints were adjudicated by independent clinical events committees. The protocols meet the criteria of the Declaration of Helsinki and were approved by the medical ethics committees of each participating institution. Written informed consent was obtained from all participating patients.

Genotyping

Blood was collected in EDTA tubes at baseline and genomic DNA was extracted following standard procedures. As a first step to investigate this gene, we selected two validated polymorphisms in the PCAF promoter. The −4556 C/T (rs2625074) and the −2481G/C (rs2948080) polymorphisms were selected on the basis of their high minor allele frequency (>5%) and measured using the Sequenom Massarray genotyping platform (Sequenom Inc, San Diego, CA, USA). A multiplex assay was designed using Assay designer software (Sequenom Inc). As quality controls, 5–10% of the samples were genotyped in duplo. No inconsistencies were observed. Cluster plots of the signals from the low and the high mass allele were drawn. Two independent researchers carried out scoring. Disagreements or
vaguely positioned dots produced by Genotyper 4.0 (Sequenom Inc) were left out of the results.

Cells and cell culture

The cell lines (HeLa, U251, Raji) used in this study were obtained through the American Type Culture Collect (ATCC) (Rockville, Maryland, USA) and were cultured in Iscove's modified Dulbecco's medium (BioWhittaker Europe, Verviers, Belgium) supplemented with 10% (v/v) heat-inactivated fetal calf serum (Greiner, Alphen a/d Rijn, The Netherlands), 100 IU/ml streptomycin and 100 IU/ml penicillin. For interferon gamma (IFN-γ) induction, cells were treated with 500 U/ml of IFN-γ (Boehringer-Ingelheim, Alkmaar, The Netherlands) for 4 h, hereafter nuclear extracts were prepared (see below). Human umbilical vein endothelial cells (HUVEC) were cultured in medium 199 with Earl's salt and 1-glutamine (Life Technologies, Breda, The Netherlands), supplemented with 20% (v/v) fetal calf serum (PAA, Pasching, Austria), 100 IU/ml streptomycin and 100 IU/ml penicillin, 10 IU/ml heparin (Leo Pharma, Breda, The Netherlands) and 25 mg bovine pituitary extract (Life Technologies).

Transcription factor binding site search

Potential transcription factor binding sites were identified using the TFSEARCH program (http://www.cbrc.jp/research/db/TFSEARCH.html), which searches the TRANSFAC database.20 Cut-off was set at 75% of the consensus transcription factor binding site.

Nuclear extracts and EMSA

Nuclear extracts and electrophoretic mobility shift assays (EMSA) were performed as described previously.29 In brief, 2 μl of nuclear extracts (HeLa, HUVEC, U251, Raji) in binding buffer were incubated for 30 min on ice, with 2 ng of a [33P]-labelled double-stranded DNA probe. The probe sequences were similar to either the C or G promoter variants of the PCAF gene (PCAF-C: 5′−CCAATTAGCCCTCCTGAACTCCTTTGCCCTTTG−3′; PCAF-G: 5′−CCAATTAGCCCTCCTGAACTCCTTTGCCCTTTG−3′). Probe sequences for transcription factors MZF1 and GATA1-3 were similar to their previously described consensus sequence (MZF1 (five fingers 1–4): 5′−GATCTTAAAGTGGGAGAAAA−3′; MZF1 (five fingers 5–13): 5′−GATCCGGCTGGTACGGGGAATCG−3′; GATA: 5′−GGACCTTTGACCTTTATCTT−3′).31

For competition assays, nuclear extracts from IFN-γ-stimulated HeLa cells were incubated with unlabelled oligonucleotides in 100 and 200-fold excess for 30 min on ice, before incubation with the labelled probe. In the case of IFN-γ-treated samples, cells from five different cell types were stimulated with IFN-γ (500 U/ml; Boehringer-Ingelheim) for 4 h before preparing nuclear extracts. Samples were run on a 6% polyacrylamide gel in 0.25×TBE buffer. Gels were densitometrically analysed using ImageJ software.32

Mouse model for reactive stenosis

The institutional committee on animal welfare approved all animal experiments. For all experiments hyperlipidaemic male ApoE−/3-Leiden mice33 were fed a high-cholesterol diet (Ariënblok, Woerden, The Netherlands). Blood samples to determine plasma cholesterol were collected at the time of surgery. After 3 weeks on the diet, a non-constrictive polyethylene cuff was placed loosely around one femoral artery and mice were killed at several time points after surgery. After they were killed, at t=0 h (control, no cuff placement), 6 h, 24 h, 2 days, 3 days, 7 days and 14 days, both femoral arteries were isolated and snap-frozen in liquid nitrogen (n=6 mice for each time point). RNA isolation and cDNA synthesis from femoral artery tissue

Per time point, cuffed segments of three femoral arteries were pooled to enable isolation of suitable amount of RNA, resulting in four pooled RNA samples obtained from n=6 mice, cuffed at two limbs. After RNA isolation, complementary DNA was synthesised and reverse transcriptase (RT)−PCR analysis was performed as previously described.34

PCAF mRNA quantification

Expression levels of PCAF were measured by virtue of quantitative RT−PCR using TaqMan gene expression assay (Mm00451387_m1). PCR runs were carried out in the ABI PRISM 7700 sequence detection system (Applied Biosystems, Foster City, California, USA). HPRT was assayed as the control gene and its cycle threshold (Ct) was subtracted from the cycle threshold of the gene of interest, yielding ΔCt. For each time point, ΔΔCt was determined by subtracting the average ΔCt at time point 0 h from the ΔCt at each other time point. This ΔΔCt was used to calculate the displayed fold increase for each gene.35

Statistical analysis

Allele frequencies were determined by gene counting. The χ² test was used to test the consistency of the genotype frequencies at the SNP locus with Hardy−Weinberg equilibrium. HR with 95% CI were calculated using a Cox proportional hazards model. All analyses with PROSPER and WOSCOPS data were adjusted for sex, age and pravastatin use. The analyses with PROSPER data were additionally adjusted for country. In the GENDER study, polymorphisms were included in a multivariable model containing clinical and procedural risk factors for restenosis, such as diabetes, smoking, hypertension, stenting, total occlusion and residual stenosis greater than 20%.

To reach statistical significance with an α of 0.05 and a β of 0.8 in the association between the −2481 polymorphism and CHD death in this population, we need 168 cases of CHD death, for the −4556 we need 579 cases of CHD death. A combined-effect analysis was performed to pool the results of the effect of the −2481G/C polymorphism on study endpoints (all-cause mortality, CHD death and clinical restenosis) and coronary endpoints (CHD death in two studies and clinical restenosis in the third study) in the three separate studies at old age. The random-effects model was used to consider both the between-study and within-study variability. The pooled HR over the genotypes was assessed with ordinary logistic regression. SPSS software (version 12.0.1) was used for all statistical analyses.

RESULTS

PROSPER study

Participant characteristics are presented in table 1. Genotyping success rates were higher than 96% for all polymorphisms and there were no significant deviations from Hardy−Weinberg equilibrium.

Using a Cox proportional hazards model, which included several clinical variables such as sex, age, pravastatin use and country, we found a significant association of the −2481G/C promoter polymorphism with all-cause mortality in PROSPER. As presented in table 2 and figure 1, heterozygotes had a reduced mortality risk by 17% (2−50%; p=0.03), whereas individuals homozygous for the −2481C allele had a 59% lower mortality
The effect of PCAF is more profound in the association with CHD death (risk reduction 22% (2–37%), p=0.05) compared with the association with cancer mortality (risk reduction 13% (9–50%), p=0.22). Due to its proximity to the −2481C/G polymorphism, we also present the data of the −4556C/T polymorphism (table 2). It shows a small and non-significant trend towards a decrease in all-cause mortality. The linkage disequilibrium coefficient between these promoter polymorphisms was 0.79.

**WOSCOPS study**

To validate the association of the −2481C/G polymorphism with CHD mortality, and to investigate whether its effect is also present in a population largely without established vascular disease, we aimed to replicate our findings in a previously described26 nested case–control cohort of the WOSCOPS study. Baseline characteristics of the WOSCOPS study are presented in table 1.

In this case, the −2481C/G polymorphism was associated with a non-significant trend towards protection against death from CHD (risk reduction 17% (−14–59%), p=0.26) at all ages. Heterozygotes (risk reduction 11% (−59–42%), p=0.62) and homozygotes (risk reduction 57% (−56–71%), p=0.24) had a non-significantly lower mortality risk. Although these data did not reach statistical significance, the point estimate for CHD mortality in WOSCOPS was similar to that observed in the PROSPER study (figure 1). The −4556C/T polymorphism was not significantly associated with the risk of CHD death (risk reduction 20% (−56–53%), p=0.40).

**GENDER study**

To extend the observed results in the PROSPER study, we tested the relevance of the gene to clinical conditions in which cell proliferation and inflammation play a role in a large patient population included in the GENDER study. In this study patients were followed for at least 9 months after a PCI to determine the absence or presence of clinical restenosis, as defined by the need for TVR. We considered TVR a suitable intermediate endpoint as it is a direct consequence of mainly proliferative and inflammatory processes.2

In agreement with the results from the PROSPER and WOSCOPS studies, the −4556C/T polymorphism was not associated with the risk of TVR in the GENDER study, whereas the −2481C/G polymorphism showed a significant association with TVR (P=trend=0.02) (table 3 and figure 1). Heterozygous patients were at lower risk of TVR (risk reduction 20% (−2–58%), p=0.07), and patients carrying two −2481C alleles had a greater protection against the development of restenosis (risk reduction 36% (0–59%), p=0.05).

In analogy of the clinical restenosis (TVR) results, carriers of the −2481C allele also had less angiographic restenosis in a subpopulation of 478 patients undergoing angiography 6 months after the PCI (risk reduction 44% (4–67%), p=0.05) (table 3).

**Combined effect analysis**

HR were almost remarkably equal in all three studies (figure 1). We formally tested for homogeneity using a standard Olkin-type Q-test and found p values of 0.91 and 0.77 for heterozygotic and homozygotic carriers of the minor allele of −2481G/C SNP between the three studies. Therefore and as all three studies have comparable endpoints, we conducted a combined effect analysis to show the effect of the −2481C on the study endpoints (CHD death in PROSPER and WOSCOPS, and clinical restenosis in GENDER) at all ages (figure 2, top panel). The pooled HR for the −2481C allele was 0.79 (95% CI 0.74 to 0.85; p =8.1×10⁻⁷). Heterozygotes had a reduced risk (HR 0.82; 95% CI 0.68 to 0.98; p=0.05), and this risk was lower in subjects homozygous for the −2481C allele (HR 0.61; 95% CI 0.44 to 0.84; p=0.002).

*Calculated for 5595 subjects in the PROSPER study and for 1092 in the WOSCOPS study.

CHD, coronary heart disease; PCAF, P300/CBP-associated factor.
Figure 1  HR for all-cause mortality in PROSPER, for coronary heart disease (CHD) death in WOSCOPS, and for clinical restenosis in GENDER by P300/CBP-associated factor (PCAF) –2481G/C genotype at all ages. The PCAF –2481G/C polymorphism is associated with mortality in the PROSPER study, with CHD death in the WOSCOPS study, and with clinical restenosis in the GENDER study in all age groups.

Examiner for an age effect

We investigated an effect of the –2481C-variant allele on vascular mortality in two age strata, older and younger than 58 years. We could not, however, perform this analysis in the PROSPER cohort because all subjects were older than 70 years. In the WOSCOPS study, among participants 58 years of age and older (median age), we found that the –2481C allele significantly reduced the risk of CHD death (risk reduction 39% (3–62%), p=0.035), whereas there was no significant effect in the lower age group. We found similar results in the GENDER study. We again observed a strong protective effect of the C-allele in old patients (>58 years, n=1800) (risk reduction 30% (12–45%), p=0.005) whereas there was no significant effect present in young patients (<58 years, n=1052).

We also conducted a combined effect analysis to show the effect of the –2481C allele at a high age only (median age >58 years), shown in figure 2 bottom panel. The pooled HR for the –2481C allele on coronary events (CHD death or TVR) in this high age group was 0.72 (95% CI 0.61 to 0.84; p=4.9×10⁻⁵), which is somewhat stronger than the effect at all ages.

DISCUSSION

Our data indicate that the –2481C allele in the gene encoding PCAF, a protein that has been shown to be a key mediator in epigenetics by acetylating histones and several non-histone proteins, such as the p53 tumour-suppressor proteins, is associated with a significant survival advantage in three independent studies. We found in the PROSPER-study an advantage in survival mainly due to a significant risk reduction in CHD death. In line with this observation we also observed that the –2481C allele was associated with a lower incidence of death by CHD in the WOSCOPS study in an age-dependent manner. Furthermore, this allele also protects against clinical and angiographic...
restenosis in the GENDER-study. The effects of the −2481C allele on mortality, CHD death and clinical restenosis were more profound at older ages (>58 years). The −2481G/C polymorphism in the PCAF promoter affects transcription factor binding, as was demonstrated by an EMSA band shift analysis. A role for PCAF in vascular disease was further confirmed in a mouse model for reactive stenosis, in which modulation of PCAF expression was detected during vascular remodelling.

Our observation in the PROSPER study that this promoter variant associates with lower mortality from cardiovascular disease and cancer as well as clinical restenosis after PCI in GENDER, may indicate a role of PCAF in inhibiting cell proliferation also in more general terms. PCAF has been shown, for example, to activate p53-responsive enhancer elements within the p21waf1 promoter, and activity of p21waf1 is known to induce cell-cycle arrest in vascular smooth muscle cells. Furthermore, A20, a NFκB-dependent gene that has been shown to inhibit proliferation of vascular smooth muscle cells by increased expression of p21waf1, was able to prevent neointima formation after balloon angioplasty in a rat model of carotid artery stenosis.

Apart from its well-described role in cell-cycle regulation, PCAF is also known to be required to co-activate p65-dependent transcription, and has been shown to activate directly the transcription of several NFκB-regulated genes known to be involved in cardiovascular disease. Miao et al have shown that PCAF could enhance the p65-mediated increase in tumour necrosis factor alpha (TNFα) promoter activity and that high glucose increased the recruitment of PCAF to the TNFα and cyclooxygenase 2 promoters. Furthermore, they demonstrated concomitant acetylation of specific lysine residues of histone H3 and H4 at these promoters. As TNFα and cyclooxygenase 2 have been implicated in the development of atherosclerosis, restenosis and also cancer, our data suggest that PCAF may also play a role in the development of these diseases.

Our finding in the WOSCOPS and GENDER studies that the strong protective effect of the −2481C allele was more profound in patients older than 58 years, whereas it seemed not to be present in young patients (<58 years old) is of particular interest. It could reveal the combined effect of a lifetime dysregulation of expression of the lysine acetyltransferase –2481IC PCAF variant, which affects global levels of histone acetylation, in addition to the accumulating effect of exposure to environmental factors that also affects histone acetylation profiles during life, as observed by Fraga et al. In the PROSPER population such an age-dependent effect was not observed as this trial included only patients over 70 years old. As expected, here the effects on cardiovascular and cancer mortality associated with the PCAF −2481G/C polymorphism were evident for the entire population. After observing an age-dependent effect in the WOSCOPS and GENDER studies, we suggest that this polymorphism in PCAF is associated with an altered tendency to acetylate histones and non-histone proteins (such as the tumour-suppressor p53, whose function relies on acetylation, reviewed in Spange et al), and may therefore become...
important especially in elderly patients, who may have been under the influence of altered PCAF activity for many years. This hypothesis, however, needs further investigation.

Although our findings in the GENDER study do not directly replicate the effect of the −2481G/C polymorphism on CHD mortality in the elderly, they are of much value as this study has a mechanistically linked and better defined concise endpoint. Therefore, in this way pathophysiologic insights would be obtained and not just replication only. Restenosis after a PCI is very well investigated and is now known to be mainly the consequence of inflammatory and proliferative processes, which is underscored by the fact that drug-eluting stents that suppress these processes are highly efficacious in the prevention of restenosis. Therefore, we believe that our finding that the −2481C allele protects against restenosis in the GENDER study could possibly confirm its functional significance, but could also provide mechanistic insights into its beneficial role in survival in the PROSPER and WOSCOPS studies. However, this could only explain part of the causes by which CHD death risk is decreased in the PROSPER and WOSCOPS studies, the exact mechanism is not known. We did not find any association between the strongly linked −4556C/T polymorphism and survival in any of the three studies. The estimated HR were quite similar as expected, however, due to small numbers because the minor allele frequency of −4556C/T is three to four times smaller than that of −2481G/C, no significant results were yielded. This could simply be due to lack of power.

Here we show a strong association between the PCAF locus involved in epigenetic control and clinical conditions in three large follow-up studies with a mechanistically linked endpoint; however, our studies warrant further investigation into the influence of the −2481G/C polymorphism on the activity of the PCAF promoter or expression levels of NFκB-regulated genes. Here we hypothesise a new concept that differential transcription of the PCAF gene leads to differences in gene expression in various pathways mechanistically linked to CHD events, such as inflammatory regulatory pathways or pathways involved in proliferation. Therefore, further research has to be performed to test this hypothesis.

In a first analysis we were able to demonstrate binding of nuclear factors to the specific region flanking the −2481G/C polymorphism in the PCAF promoter. EMSA analysis showed that the G-variant possibly exhibits a slightly higher affinity for nuclear factor binding than the C-variant in some cell types tested (eg, HUVEC and U251), albeit that this was not significant. It should also be noted that IFN-γ stimulation slightly increases nuclear factor binding in HUVEC and U251 cells, suggesting a role for IFN-γ-induced nuclear factors. It remains to be established whether these interacting factors play a role in the transcriptional regulation of PCAF. However, provided that this SNP influences PCAF transcription and resulting protein levels, this could have a bearing on the cellular portrait of expressed genes and might lead to a dramatically different outcome if the effects accumulate over years. The fact that nuclear extracts do bind to the same region of the promoter in which the polymorphism is situated does strongly suggest that the SNP might affect the binding of transcription complexes and thus influences gene transcription; however, this needs to be confirmed in future studies.

To illustrate further a possible role of PCAF in vascular disease, we quantified PCAF transcripts in the stenotic vessel wall in a mouse model of cuff-induced reactive stenosis in the femoral artery. During the stenotic process, PCAF gene expression was rapidly upregulated, indicating that PCAF gene expression is activated upon vascular injury and suggesting that this transcriptional coactivator is involved in the development of reactive stenosis, at least in the early stages. Unfortunately, it is not possible to measure the PCAF protein levels directly; however, the rapid up and downregulation of the messenger RNA levels suggests that PCAF is not stable. The changes in mRNA levels are likely to reflect the changes in protein levels.

In conclusion, we showed in three large prospective studies that the −2481C allele in the PCAF promoter is associated with a significant survival advantage in elderly patients while also protecting against clinical and angiographic restenosis after PCI. Although the exact mechanisms of these actions are thus far unknown, we suggest that the effect of this allele on these endpoints may be due to the well-known involvement of PCAF in inflammatory and proliferative processes. Our observations promote the concept that epigenetic processes are under genetic control and that, other than environment, genetic variation in genes encoding KAT may also determine susceptibility to CHD outcomes and mortality. Therefore, epigenetic histone modification, when our results are confirmed in our studies, might become a target for future therapy.
