The interplay of quantum statistics, interactions, and temperature is studied within the framework of the bosonic two-component theory with repulsive delta-function interaction in one dimension. We numerically solve the thermodynamic Bethe ansatz and obtain the equation of state as a function of temperature and of the interaction strength, the relative chemical potential, and either the total chemical potential or a fixed number of particles, allowing quantification of the full crossover behavior of the system between its low-temperature ferromagnetic and high-temperature unpolarized regime, and from the low coupling decoherent regime to the fermionization regime at high interaction.

I. INTRODUCTION

The increasingly common experimental realization of interacting quantum systems using cold atoms has recently reignited interest in pushing our understanding of many-body physics beyond the traditional mean-field level [1]. This aspect is most prominent in effectively one-dimensional realizations of bosonic 87Rb quantum gases with tunable interaction strength [2–6], for which the whole crossover from weakly to strongly interacting physics is accessible.

The case of locally interacting atoms confined to a uniform one-dimensional channel has the theoretical peculiarity of being integrable. The simplest case of a single bosonic species defines the well-known Lieb-Liniger model [7,8] for which a recent experimental study has shown that the observed thermodynamic properties [9] or system fluctuations [10,11] can be understood from the theory of integrable systems at finite temperatures. In order to study even richer highly correlated systems, multicomponent (spinor) gases have been experimentally realized [12–14]. This extension involves different hyperfine states which provide a pseudospin degree of freedom [15–18]. Control of the intra- and interspecies interaction strength via Feshbach resonances or state-dependent potentials [19–21] opens the way for realizing a variety of integrable models.

The main interest in pursuing the study of multicomponent systems is that they provide situations where important interaction and quantum statistics effects coexist. These two aspects are not unrelated, even in single-component systems: as a simple illustration, for a single bosonic species in one dimension, the limit of infinitely strong interactions (impenetrable bosons) causes a crossover from bosonic to effectively fermionic behavior [22,23], at least for physical quantities of density type. Considering more than one component, however, opens the door to much richer effects, such as the presence of spin-wave excitations, with the possibility of crossover to many more regimes than the one-component case.

The study of multicomponent integrable systems really begins with the spin-1/2 fermion problem [24–28]. An interesting feature of this system is that the attractive case has a correspondence to a bosonic system with twice the interaction, in the sense that the equation for the ground state and particle energy coincide up to a sign [28]. A fundamental step forward was thereupon achieved by Yang, who showed that the repulsive δ-function interaction problem admitted an exact solution irrespective of the symmetry requirement imposed on the wave function [29]. For spin-1/2 particles, he showed that a generalized Bethe hypothesis in the form of what is today called a nested Bethe ansatz could provide the system’s wave functions, obtained the continuum equations for the ground state, and calculated the general bound-state S matrices [30]. Sutherland [31] generalized this to any irreducible representation of the permutation group, so that particularly systems of type (in his notation) $B^x F^y$ with $x$ species of bosons and $y$ species of fermions were amenable to an exact solution [32]. The ground state and excitations of multicomponent fermionic systems were studied, both for repulsive and attractive interactions, by Schlottmann [33,34]. This made extensive use of the “string hypothesis” for the solutions to the Bethe equations, yielding the various dispersion branches in the repulsive case, and the gapped color singlet ground states in the attractive one.

The bosonic multicomponent case has been less extensively studied. For two components and in contrast with the Fermi gas, the ground state is (pseudospin) polarized as expected from basic arguments [32] or more formally from a general theorem valid when spin-dependent forces are absent [35]. In pseudospin language, the ground state is thus ferromagnetic, and the excitations at large coupling correspond to those in an isotropic $XXX$ ferromagnetic chain [36], revealing thermodynamic properties which are drastically different from those of the one-component Lieb-Liniger gas [37,38]. Furthermore, recent studies of the ferromagnetic ground state revealed different dispersions for the charge and pseudospin excitations, which therefore exhibit a spin-charge separation [39,40]. The regime of strong interaction is still not completely understood, and even if Girardeau’s Fermi-Bose mapping has been shown and used for the study of the one-dimensional (1D) spinor Bose gases [41] leading to a paramagnetic Tonk-Girardeau regime [36], this approach fails to provide first correction terms to this fermionization regime since the discernability of the bosons is missing.

The purpose of our paper is to further stimulate the contact between integrability theory and experiments on multicomponent cold atoms by providing quantitative predictions for the equation of state and population densities of two-component
where the gas enters the fermionization regime. We end with where we compare the numerical results with a perturbative discuses the results in the decoherent regime of low coupling on the more challenging intermediate regimes. Section VI approaches allowing cross-checking of the results. Section VII presents the results at strong coupling where the gas enters the fermionization regime. We end with conclusions and perspectives.

II. SETUP

Consider a collection of bosonic atoms of equal mass but having an internal SU(2) degree of freedom (in practice, this would be, for example, two distinguishable hyperfine states and could be thought of as a (pseudo-)spin-1/2). The unique feature differentiating from a single species is the fact that distinguishability imposes symmetry of the many-particle wave function on the same-spin particles only. For definiteness, we consider a one-dimensional ring of length $L$ in which a total of $N$ atoms circulate. The first-quantized Hamiltonian of the system includes a free dynamical term to which a spin-blind interaction term is added, and reads

$$H_N = -\frac{\hbar^2}{2m} \sum_{i=1}^{N} \frac{\partial^2}{\partial x_i^2} + g_{1D} \sum_{1 \leq i < j \leq N} \delta(x_i - x_j).$$

(1)

The effective one-dimensional coupling parameter $g_{1D}$ is related to the effective 1D scattering length $a_{1D}$ via the relation $g_{1D} = \hbar^2 a_{1D}/2m$. Hereafter we use the effective interaction parameter $c = g_{1D}m/\hbar^2$ and adopt the traditional convention of setting $\hbar = 2m = 1$ to simplify the notations. Note that this choice of interaction term involves fine-tuning two parameters: more generally, we could have different intra- and interspecies scattering lengths. To preserve integrability, however, these must all be equal.

Specializing to $N$ atoms of which $M$ have (in the adopted cataloguing) spin down, the Bethe ansatz provides eigenfunctions fully characterized by sets of (quasimomenta) $k_j, j = 1, \ldots, N$ and pseudospin rapidities $\lambda_\alpha, \alpha = 1, \ldots, M$, provided these obey the $N + M$ coupled equations [29,31]

$$e^{ik_j L} = -\sum_{i=1}^{N} \frac{k_j - k_i + i\epsilon}{k_j - k_i - i\epsilon - \frac{\pi}{2}} \prod_{a=1}^{M} \frac{k_j - \lambda_a - i\epsilon}{k_j - \lambda_a + i\epsilon + \frac{\pi}{2}} + \prod_{i=1}^{N} \frac{\lambda_\alpha - k_j - i\epsilon}{\lambda_\alpha - k_j + i\epsilon + \frac{\pi}{2}}$$

$$- \prod_{i=1}^{N} \frac{\lambda_\alpha - k_j - i\epsilon}{\lambda_\alpha - k_j + i\epsilon + \frac{\pi}{2}} = -\prod_{i=1}^{M} \frac{\lambda_\alpha - \lambda_\beta - i\epsilon}{\lambda_\alpha - \lambda_\beta + i\epsilon + \frac{\pi}{2}}$$

for $j = 1, \ldots, N$ and $\alpha = 1, \ldots, M$. For a generic eigenstate, the solution to the Bethe equations is rather involved and cannot be obtained in closed form. Two observations allow to push the treatment further: first, for $c > 0$, the $k_j$ rapidities live on the real axis. This is not true of the $\lambda_\alpha$, which are found to be generically complex but arranged into regular patterns called strings [44,45]. An $n$ string of $\lambda$’s is a congregation of $n$ rapidities sharing the same real value and having an even spacing of height $c$ in the imaginary direction. The adopted notation for the $\alpha$th member of an $n$ string labeled by the index $\alpha$ and centered on $\Lambda_\alpha^n$ is thus $\lambda_\alpha^n = \Lambda_\alpha^n + i(\pi(n + 1 - 2\alpha))$, with the equality being exact only up to deviations which (according to the traditional string hypothesis) vanish in the infinite size limit. Throughout our work we adopt this as a working hypothesis. Since the total number of each type of string is conserved under time evolution, each string type represents a quasiparticle of the theory. In the thermodynamic limit, the distribution of all rapidities can be encoded into a set of smooth functions representing the densities of roots for each string type. The Bethe equations then become a set of coupled integral equations for (quasi-) particle and (quasi-) hole root distribution functions. We refer the reader who is unfamiliar with these to our summary of important formulas in Appendix A.

The thermodynamic Bethe ansatz (TBA) allows exploitation of the condition of thermal equilibrium [46,47] to obtain the Yang-Yang-Takahashi (YYT)–like equations [36,37,47] for $\epsilon(k)$, the dressed energy, and $\epsilon_n(k)$, length $n$ string dressed energy, $n = 1, 2, \ldots$

$$\epsilon(k) = k^2 - \mu - \Omega - T a_2 \ast \ln[1 + e^{-\epsilon(k)/T}] - T \sum_{n=1}^{\infty} a_n \ast \ln[1 + e^{-\epsilon_n(k)/T}]$$

$$\frac{\epsilon_1(k)}{T} = f \ast \ln[1 + e^{-\epsilon(k)/T}] + f \ast \ln[1 + e^{\epsilon(k)/T}]$$

$$\frac{\epsilon_n(k)}{T} = f \ast \ln[1 + e^{\epsilon_n(k)/T}] + f \ast \ln[1 + e^{\epsilon_1(k)/T}] \quad (n > 1),$$

(3)

with the standard convolution notation $g \ast h(k) \equiv \int_{-\infty}^{\infty} dk^\prime g(k - k^\prime) h(k^\prime)$, and the kernels $a_n(k) = \frac{1}{2\pi} \frac{\pi n/2}{\cosh(\pi n/2)}$ and $f(k) = \frac{1}{2\pi} \frac{\pi k}{\cosh(\pi k/2)}$. The set of coupled equations is completed with the asymptotic conditions

$$\lim_{n \to \infty} \frac{\epsilon_n(k)}{n} = 2\Omega$$

for high-level functions. From these can be derived the large-rapidity asymptotes

$$\lim_{k \to \infty} \epsilon_n(k) \equiv \epsilon_n^\infty, \quad n = 1, 2, \ldots$$

(4)

(5)

for the large-rapidity asymptotic values of the individual functions, where we have defined the numbers

$$\epsilon_1^\infty \equiv 2\Omega n + T \ln\left[\frac{1 - e^{\mp \pi/2(n+1)}}{1 - e^{-\mp \pi/2}} \right] - e^{-2\pi n/\Omega}.$$
to the \(i\)th component, and relative \(\Omega = (\mu_{\text{i}} - \mu_{\text{f}})/2\) chemical potential (see Appendix C concerning the \(c\) parameter). The Gibbs free energy per unit length is given by

\[
g = -\frac{T}{2\pi} \int_{-\infty}^{\infty} \ln[1 + e^{-e(k)/T}] \, dk, \tag{7}
\]

while the linear density of the \(i\)th boson component is

\[
n_i = -\frac{1}{2} \left[ \frac{\partial g}{\partial \mu} + (-1)^{i-1} \frac{\partial g}{\partial \Omega} \right]. \tag{8}
\]

The entropy density is given by the standard thermodynamic identity

\[
s = -\frac{\partial g}{\partial T}, \tag{9}
\]

and the local density-density correlator \([48,49]\) is given (using the Hellman-Feynman theorem) by

\[
g^{(2)} = \frac{\sum_{i,j} \langle \Psi_i^\dagger \Psi_j^\dagger \Psi_i \Psi_j \rangle}{\left( \sum_i \langle \Psi_i^\dagger \Psi_i \rangle \right)^2} = \frac{-g_{\mu}}{\pi}. \tag{10}
\]

III. NUMERICAL TREATMENT

To solve the infinite system of transcendental coupled Eq. (II), we have developed two different numerical algorithms. We can then independently check the results by numerical treatment. Afterward we describe and motivate the comparison. We first discuss the common approach for the algorithms. We can then independently check the results by iteration approaching but not reaching the solution leads to inaccuracy.

The imprecision is limited as described hereafter. The discretization of the functions adds an error \(O(\frac{1}{N})\) in the convolutions \((N\) being the numbers of points), which induces an imprecision that one can easily keep low. Concerning the range cutoff, all the thermodynamic quantities are \(\propto e^{-e(k)/T}\), with \(e(k) = k^2\) when \(k \gg 1\). Therefore we reduce this effect on the results by taking an appropriate \(k\) spacing such that \(\Delta^2 / T \gg 1\). Finally, as we can see from Eqs. (3), (B)–(B3), all the contributions of the \(e_n\) functions in \(e(k)\) are \(\propto e^{-e_n(k)/T}\). Knowing that for \(n \gg 1\), \(e_n(k) \cong 2\pi n\), we therefore keep this imprecision small by choosing \(\frac{2\pi n}{T} \gg 1\). In the results shown in all plots, the precision of the results is estimated to always be much smaller than the width of the curves.

The problem is different for the accuracy. Supposing that the solutions \(\{e, e_1, e_2, \ldots\}\) \((\var \in \{\mu, \Omega, T, c\})\) exist, we suppose that by iteration we approach these solutions but the distance from the solution is nevertheless unknown. We estimate the accuracy empirically. By increasing the total number of iterations exponentially, we observe the convergence of the results and judge the accuracy value. In the following results, the accuracy is estimated to be of order of the linewidth and therefore globally is the higher limitation on exactitude of the results.

C. Fast-Fourier-transform–based algorithm

1. Idea

During the iterative process, the major part of calculation time is taken by the evaluation of each convolution. Indeed, by calculating the integrals by simple trapezoidal sums, this charge represents \(\propto O(N, N_{\text{max}})\) operations for each function. Starting from this observation, the basic idea of this algorithm is to use the fast-Fourier transform (FFT) algorithm to calculate the convolution: \((f \ast g)(x) = \text{FT}^{-1}[\text{FT}(f) \ast \text{FT}(g)]\). The computing time of each convolution using FFT is thus only \(\propto O(N, \ln(N))\). The conditions of use of the FFT are that the functions \(f\) and \(g\) must be integrable and that the values of these functions must be zero outside \([-\Delta_n : \Delta_n]\). This could be easily achieved by treating the constant part of the function separately from the nontrivial part. Moreover, this method imposes the numerical constraints that all the points must be equally spaced and that the range and the numbers of points of each function must be the same.

2. Practically

As a consequence of this, we have a set of \(n_{\text{max}} + 1\) functions each to be evaluated on \(N\) points and within the
D. Flexible-density method

A second, completely independent implementation of the numerical solution to the coupled integral equations has been pursued as part of our work. Here we do not make use of the fast-Fourier transform, but rather maintain total flexibility in the choice (1) of density of sampling points within each function, (2) of the $\Delta_i$ limits used at each level, (3) of the relative total number of points used at each level, and (4) of the total number of functions used. This advantage allows one to concentrate computational resources where they are needed, but comes at the cost of being able to perform only convolutions between, e.g., levels $i$ and $j$ at speed of order $N_i N_j$, where $N_i$ is the number of points used at level $i$. This second algorithm performs more or less equally well as the first, and allows one to certify the results obtained.

In summary, this second algorithm works as follows. Depending on the physical parameters requested, an initial choice is made of the number $n_{\text{max}}$ of functions to be considered and of the limits $\Delta_i$ at each level. A dynamical parameter called the running precision is initialized, which estimates the numerical accuracy obtained in computing the free energy using the points configuration used. The coupled equations are then iterated (possibly using extrapolations) in order to achieve a certain degree of convergence, measured by the condition that the total rate of flow of all points as the iterations proceed becomes smaller than the running precision.

At this point, a cycle is initiated. This entails a number of steps, with the objective of increasing the accuracy, i.e., of decreasing the running precision achieved. First, each function is examined in turn, and points are added in regions with larger curvature. Second, the limits $\Delta_i$ are extended (and points added) if the value of the function at the previous limit is not sufficiently close to its analytically determined asymptotic value $\varepsilon_i^\infty$. Third, new functions are added (i.e., $n_{\text{max}}$ is increased) if the highest function is not sufficiently close to its asymptotic value throughout the $k$ line. A new value of the running precision is then determined, based on the refinements just performed on the distribution of points. Finally, iterations are performed until the flow rate drops below this running precision.

For a specific set of physical parameters, a total allowed time is also given to the program. This second implementation then performs cycles one after the other, yielding increasingly accurate results, until the allowed time is exhausted. An estimate of the absolute accuracy of the whole procedure can thus be obtained by comparing the results from runs with different total allowed times.

IV. QUANTUM STATISTICS VERSUS TEMPERATURE FLUCTUATIONS

The SU(2) degree of freedom in combination with the bosonic statistics in 1D leads to a macroscopic behavior: polarization of the ground state. This phenomenon, which occurs in every bosonic system with no explicit component-dependent forces, has been already proven in the literature [35]. Here we give an interpretation in terms of the string structure of the Bethe equation solutions and provide a quantitative result for the persistence of this effect for nonzero temperature.

The polarization at zero temperature can be directly linked to the underlying string structure of the Bethe equation solutions. In Eq. (II), the $\varepsilon(k)$ function depicts the charge degree of freedom and the $\varphi(k)$ functions the spin degrees of freedom. Moreover, those latter functions express the dynamics of a quasiparticle forming a color 2 energetically disfavored state made of $n$ particles. As the temperature of the system goes down, the contribution of these states in the equilibrium decreases.

We hereafter explain how at the limit $T = 0$ there only remains one spin-gapped state gathering all particles in the

\[ \sigma_{\text{fit}} = -\frac{T}{2\pi G} \sum_{i=1}^{N} \ln \left[ 1 + \exp \left( -\frac{\varepsilon_n(k_i)}{T} \right) \right] \]

With $\varepsilon_n(k_i)$ being the value of $\varepsilon(k_i)$ after $n$ iterations. This formula has to be understood as the variation of the Gibbs free energy between two steps [see Eq. (7)]. We measure similarly the parameter $\varepsilon_n(k_{N_i})$.

During computation, if $\sigma_{\text{fit}} > \sigma_{\text{fit}}$, $n_{\text{max}}$ is increased and if $\sigma_D > \sigma_{\text{fit}}$, $\Delta$ is lengthened. The precision related by the density of points $D$ is hard to quantify but can be estimated by cross-checking with the second method, which has a nonuniform distribution of points. We then increase step by step as one goes along the iterating process.

Once satisfactory values for $\sigma_{\text{fit}}$, $D_{\text{fit}}$ are achieved, we assume the solution has been reached and we calculate the Gibbs free energy from Eq. (7). The derivatives of the Gibbs free energy are computed using the derivative systems [Eqs. (B1)–(B3)], with the final $(\Delta, n_{\text{max}}, D_{\text{fit}})$ determined by the first iterative process, and we approximate the precision during the iterations by

\[ \sigma_{\text{var}} = \frac{1}{2\pi} \sum_{i=1}^{N} \Delta_i \left| \frac{\partial \varphi(k_i)}{\partial \varphi} - \frac{\partial \varepsilon(k_i)}{\partial \varepsilon} \right| \frac{1}{1 + \exp \left( \frac{\varepsilon(k_i)}{T} \right)} \]

Since the arbitrary $\sigma_{\text{var}, \text{fit}}$ with $D_{\text{fit}}$ are reached, we consider that we have a good evaluation of the solutions.
FIG. 1. (Color online) The top graph shows polarization of the 2CBG, \( (n_1 - n_2)/(n_1 + n_2) \), for fixed density of particles and interaction strength (\( \gamma \)) as a function of the reduced temperature (\( \tau \)). The set of curves for several different \( \Omega \) is compared to the curves of a free-spins paramagnet. The bottom plot shows the isobar polarization as a function of temperature for four different chemical potentials: \( \{-100, 0, 100, 200\} \). In this latter graph, the density \( \gamma \) and \( \tau \) vary along the curves.

FIG. 2. (Color online) For \( \gamma \ll 1 \) and \( \tau \ll 1 \), the 2CBG chemical potential follows Popov’s expression for the zero-temperature Lieb-Liniger case.

FIG. 3. (Color online) The specific heat of the 2CBG for fixed density of particles and interaction strength as a function of the reduced temperature. The different chemical potentials of each curve have a value close to \( \gamma \). Similarly to a free 2CBG case, we see a peak in the specific heat whose position depends on \( \Omega \).

first component. In the YYT equations (II), where the \( \varepsilon_n(k) \) are the dressed energies of an \( n \) string, a phenomenological approach to \( T = 0 \) is possible. Taking the first line of (II) and approximating the values \( \varepsilon_n(k) \approx 2n\Omega \), if one takes the limit \( T \to 0 \), \( T \sum_{n=1}^{\infty} \ln[1 + \exp(-2\varepsilon_n/kT)] \to 0 \) as \( \Omega \) is defined positive. The contribution of the color-2 particles then disappears from the thermalized state, and this reveals that the color-1 component drives away all color-2 particles, forming a fully polarized spin-gapped state. (In the Bethe equations, only the second component part of the wave function is represented by quasiparticles). We show this expelling in Fig. 1, where we plot polarization curves (bottom set) as a function of \( \mu \).

As the chemical potential increases, the interaction parameter \( \gamma = (\pi n^2 c)/20 \) decreases monotonically and the polarization persists to higher temperatures. In [40], Fuchs et al. revealed that the effective mass of an isospin wave above the polarized ground state is very high in the strong coupling regime. Furthermore, it is surprising to see that when \( \mu \) increases, the polarized ground state is more resistant to thermal fluctuation, even though the isospin wave mass decreases.

In the context of spontaneous imbalance in binary mixtures [50–52], it has been shown that at zero temperature, a mixed gas is unstable and exhibits a spatial phase separation, but no quantitative predictions have been made for finite temperature in 1D. From Fig. 1 we see that the polarization remains at higher temperatures for high value of \( \mu \). By qualitative identification of the ferromagnetic behavior with the spatial demixing, we can speculate that a phase separation would resist temperature variations better in the low-coupling regime than for \( \gamma \gg 1 \).

Figure 1 also shows polarization curves for fixed particle density, interaction strength, and fixed \( \Omega \) as a function of the reduced temperature \( \tau = T/T_D \), where \( T_D = (n_1 + n_2)^2 \) is the degeneracy temperature [48]. We compare these results with the polarization of a free-spin paramagnet, which is \( n_1 - n_2 = \tanh(2\Omega/k_BT) \).

The non-negligible difference which appears between the curves of the same \( \Omega \) is the ferromagnetic effect, which is a consequence of the bosons interaction.
As shown in Fig. 2, by lowering the reduced temperature of the gas to $\tau \ll 1$, the total chemical potential corresponds to the zero-temperature low-coupling-regime formula. Moreover, in this particular regime, the corresponding polarization lines turn out to be almost constant along $\gamma$.

The specific heat capacity of the gas at fixed density of particles which is accessible via the entropy (9) provides a view of the thermal degrees of freedom of the system. Figure 3 shows that in a 2CBG at low temperature with strong $\Omega$, the heat capacity is similar to that of a Lieb-Liniger Bose gas contributed by phonons. If the relative chemical potential is lower or of order of the temperature, the two-component degree of freedom appears and creates peaks similarly to a paramagnetic spinor Bose gas [36]. The maximum in the specific heat moves in higher temperature as the relative chemical potential increases. The higher temperature results are shown in Fig. 4, where we can observe that the peaks are located when $\Omega \sim T$. At high temperature the gas becomes decoherent classical (see Sec. VI), and the specific heat converges to $1/2$, which is the value of the simple 1D ideal gas.

Experiments trapping $^4$He fluid into 1D nanopores [54] provide a possible realization of the 1D Bose gas and give access to measurement of the heat capacity of the unidimensional system. A similar realization with an isospin $1/2$ might be possible and could provide measurement of the 2CBG heat capacity.
V. RESULTS IN THE INTERMEDIATE REGIME

In this section we will present the results that do not belong to a limit regime. Furthermore, in those parameter ranges, we give numerical results for the polarization of the 2CBG and the local pair correlator, where neither the thermal, the charge, nor the phase fluctuations dominate. They compete in the 2CBG state and therefore no perturbative approach but only the thermodynamic Bethe ansatz can predict a solution. We will discuss and describe as much as possible the changes in behavior that occur in these intermediate regimes.

The set of graphs in Figs. 5 and 6 show the behavior of the 2CBG as a function of $\gamma$ and any fixed value of $\Omega, T$. The values of $\Omega$ and $T$ are chosen such that in each case the ratio $T/\gamma$ goes from less to more than 1. Following the qualitative description of [48,49] for the single-component case, the regimes of the gas are identified by the two dimensionless parameters $\gamma = \frac{c}{n_1 + n_2}$ and $\tau = \frac{T}{\gamma}$, respectively, the interaction strength and the reduced temperature. As results presented hereafter are made for the fixed interaction parameter ($c$), the ratio $\frac{c}{\Omega}$ is then constant and the regime is identified by the position on the $\gamma$ axis. At the lowest value of $\gamma$, $\gamma \lesssim \tau \ll 1$ and the gas quasicondenses in a Gross-Pitaevskii (GP) regime with thermal fluctuations. At the other end, where $\gamma > 1$, the regime is decoherent classical (DC) with $\tau \gg 1$ and $\gamma$ is small, the gas quasicondenses and the regime is identified by the position on the $\gamma$ axis. In the case of a quasicondensate, we see progressively the ferromagnetic effect with a completely polarized gas, whereas the polarization reaches the value of an ideal paramagnetic gas when the 2CBG becomes DC. From this simple view of the data, we can try to see how the temperature and the relative chemical potential modify these phenomena.

The first column of Fig. 5 shows the effects of temperature on the polarization. In the region where $\gamma < 1$ the linear density of each component is almost classical and the asymptotic value of the curves are given by $\frac{\rho_0}{\rho_0^\infty} = \frac{c}{\sqrt{T}}$ (see Sec. VI). Here the charge and cohearent fluctuations are large and hence the statistics and the interaction of the gas do not play a role (the observables depend only on the temperature and chemical potentials). In contrast, for $\gamma \ll 1$ the gas quasicondenses and the charge fluctuations vanish. The ratio $\tau/\gamma^2$ being large, the temperature fluctuations exceed the phase fluctuations and we see that $T$ does not influence the polarization much.

The second column of data shows the variations of the polarization as a function of $\Omega$. The spontaneous ferromagnetism in the presence of the quasicondensate happens in high interaction strength when the relative chemical potential increases. In the YYT equations (II), the effect of $\Omega$ on the strings appears through the asymptotic value of the contribution of the $n$ strings: $T \sum_{n=1}^{\infty} \ln[1 + \exp(-2\Omega n)]$. When $\Omega$ increases, the color-2 spin-gapped state effect are suppressed and the polarization resists higher charge fluctuation (higher $\gamma$).

Figure 6 shows the local density-density correlation function as a function of $\gamma$ for different values of the relative chemical potential and temperature. On the top graph the ratio $\tau/\gamma^2$ is fixed; for $\gamma \ll 1$, the 2CBG is thus in a quasicondensate with important thermal fluctuations. In this regime the gas is ferromagnetic and $\Omega$ has no effect on the correlation. On the other hand, for large values of $\gamma$, the gas is DC and the asymptotic value of $g^{(2)}$ follows from Wick's theorem and the Boltzmann distribution, $g^{(2)}_\infty = 1 + \sum \epsilon^{2\beta\mu}_i \langle \sum \epsilon^{2\beta\mu}_i \rangle$. The first-order corrections are calculated later (Sec. VI). In the bottom figure, the curves for different temperatures show the nonmonotonic behavior discussed in [42]. Close to the quasicondensate regime, the pair correlation increases with temperature: in the DC regime temperature has a destructive role on the correlation.

VI. DECOHERENT REGIMES

In the limit of the weakly interacting Bose gas ($\gamma \ll \min[\tau^2, \sqrt{T}]$) or in the high-temperature regime ($\tau \ll \max[1, \gamma^2]$), the phase and density fluctuations are large. Therefore one can notice that in the YYT equations (II), the limit of either high temperature $T^{-1} = \delta \ll 1$ with finite $c$, or low coupling $c = \delta \ll 1$ with $T \neq 0$, one recovers the thermodynamics of two ideal Bose gases up to $\mathcal{O}(\delta^2)$. In this limit the convolutions of a function $g$ with the kernels described in Eq. (II) become

$$a_n \ast g(k) = \int_{-\infty}^{\infty} dk' \frac{1}{\pi} \frac{nc/(2\sqrt{T})}{[nc/(2\sqrt{T})]^2 + (k - k')^2} g(k'\sqrt{T}) = g(k\sqrt{T})$$

$$f \ast g(k) = \int_{-\infty}^{\infty} dk' \frac{\sqrt{T}}{\cosh\left[\frac{\sqrt{T}}{2}(k - k')\right]} g(k'\sqrt{T}) = cg(k\sqrt{T}).$$

033604-7
Furthermore, the Gibbs free energy resulting from this simplified system is

\[
\frac{G}{L} = -\frac{T}{2\pi} \int_{-\infty}^{\infty} \ln[1 + e^{-\tau(k)/T}] \, dk
\]

\[
= \frac{T}{2\pi} \int_{-\infty}^{\infty} \ln[1 - e^{-(\mu_1 - \gamma)/T}] \, dk
\]

\[
+ \frac{T}{2\pi} \int_{-\infty}^{\infty} \ln[1 - e^{-(\mu_2 - \gamma)/T}] \, dk,
\]

which is the sum of the Gibbs energy of two ideal Bose gases.

First-order corrections can then be effectively described using perturbation theory, and the reduced temperature \( \tau = \frac{T}{\hbar \omega n^0} \) allows one to distinguish between the decoherent quantum regime (DQ) for \( \sqrt{\gamma} \ll \tau \ll 1 \) and the DC regime with \( \tau \gg \max[1, \gamma^2] \) [48,49,55].

We use Feynman diagrams to express the perturbed Gibbs free energy. An explicit expression is then calculated for the local pair correlation function \( g^{(2)} \) in the two decoherent regimes (DQ & DC) to first order.

The partition function of the 2CBG in the Feynman path integral formalism is

\[
Z = \int D(\Psi, \Omega) e^{-S(\Psi, \Omega)}
\]

\[
S[\Psi, \Omega] = \int_0^\beta d\tau \int dr \sum_a \Psi_a \partial_\tau \psi_a - H(\psi, \tau),
\]

where \( \Psi(\tau, r) \) is a space and imaginary time-dependent spin-1/2 field and \( H \) is the Hamiltonian density from Eq. (1).

At first order, the correction to the Gibbs free energy following from Wick’s theorem is \( G^{(1)} = 2c[n^0 - n_0^0 n_1^0] + O(c^2) \), with the free linear density of the \( \alpha \)th component \( n_0^\alpha = \frac{T}{\hbar \omega_{\alpha} - \hbar \omega + 2m + \mu_\alpha} \) and the total free linear density \( n^0 = \sum_\alpha n_0^\alpha \). For the second order in \( c \), the diagrammatic representation gives five contributions shown in Fig. 7 that give the free-energy-density corrections

\[
G^{(2)} = -\frac{c^2}{2} \left[ 8 n^0 \sum_b n_0^b \partial_\tau n_0^b + 4 n^0 \sum_b \partial_\tau n_0^b \right] + 4 \sum_a \left( n_0^a \partial_\tau n_0^a \right) + 2 \sum_{a=0,1} \left( \bar{P}_{a,a} + \bar{P}_{a,a} + \bar{P}_{a,a} \right)
\]

\[+ O(c^3), \quad (20)\]

where the first three terms correspond to the diagrams (b), (a), and (d), while the free linear density is \( n_0^\alpha = \frac{\sqrt{\hbar \omega_{\alpha}}}{\pi \beta \mu_{\alpha}} \). The local pair correlation results from Eq. (10), and an analytic expression as a function of \( c, T, \mu_i \) is given in the two decoherent regimes. In the DQ regime, \( \sqrt{\gamma} \ll \tau \ll 1 \) and \( \mu_1, \mu_2 \ll T \), by taking the leading order in the Bose occupation number, the free linear density is \( n_0^\alpha = \frac{1}{\beta \hbar \omega_{\alpha}} \), and the double-polarization bubble is \( P_{a,b} = \frac{n_0^a n_0^b}{\sqrt{n_0^a n_0^b}} \). For a compact notation we define the \( \alpha \)th component reduced temperature by \( \tau_\alpha = \frac{T}{n_0^\alpha} \).

We thus find the local pair correlation to be

\[
g^{(2)} = \frac{n_0^0 + \sum_\alpha n_0^\alpha}{n_0^0} + 4 \gamma \left( \frac{2}{\tau_1 \tau_2} - \frac{1}{n_0^0} \left( \frac{n_0^1}{\tau_1} + \frac{n_0^2}{\tau_2} \right) \right)
\]

\[+ \frac{4}{\sqrt{\tau_1 \tau_2}} \left( 1 - \frac{n_0^1 \sum_\alpha n_0^\alpha}{n_0^0} \right) + O(\gamma^2).
\]

(22)

In the DC regime, \( \tau \gg \max[1, \gamma^2] \) and \( \mu_1, \mu_2 \gg T \), the bosonic occupation number becomes the Boltzmann distribution, and \( n_0^\alpha = \sqrt{\frac{T}{\beta \hbar \omega_{\alpha}}} \cdot P_{a,b} = n_0^a n_0^b \sqrt{\frac{\tau_2}{\tau_1}} \). The pair correlator becomes

\[
g^{(2)} = \frac{n_0^0 + \sum_\alpha n_0^\alpha}{n_0^0} + \frac{\sqrt{\tau_1 \tau_2}}{\gamma} \left( \frac{1}{\sqrt{\tau_1}} + \frac{1}{\sqrt{\tau_2}} \right) \left( \frac{n_0^0 + \sum_\alpha n_0^\alpha}{n_0^0} \right)
\]

\[+ \frac{4\gamma}{\sqrt{\tau_1 \tau_2}} \left( 1 - \frac{n_0^1 \sum_\alpha n_0^\alpha}{n_0^0} \right) + O(\gamma^2).
\]

(23)

In order to illustrate this result, we compare the value of \( g^{(2)} \) computed to the first order in \( \gamma \) [Eqs. (22) and (23)] with the numerical results using Eq. (10) in Fig. 8. The curves calculated at fixed particle density and reduced temperature show that the numerical results follow the analytical expansion nicely until either the thermal fluctuations become too strong for the DQ gas (\( \gamma \sim 10^{-3} \)) or the charge fluctuations become important in the DC regime when \( \gamma \sim 10 \). As the interac-
tion strength increases, we progressively switch to a high-
temperature Tonks-Girardeau–like fermionization regime for
the DC curves and to a ferromagnetic fermionization for the
DQ case. It would be interesting as well to compare the results
for a DQ gas in very low Ω such that the polarization is low
and $g^{(2)}$ reaches the value 3/2, but this implies a calculation
for a very high number of functions, $n_{\text{max}}$ with a large number
of points. We then could not afford the number of iterations
necessary to have a converged solution.

VII. TONKS-GIRARDEAU REGIME

In the extreme case of impenetrable particles ($\gamma \to \infty$),
Girardeau [23] showed the correspondence between impen-
terable Bose and Fermi wave functions. While the statistics
of the bosons wave function remains symmetric, there is no
more overlap between the neighbor particles. In the case of
2CBG, the charge part of the wave function behaves like
a one-component free fermion gas and noninteracting dis-
tinguishable spin-1/2 since any spin-spin exchange vanishes
[36,41,46]. In both 1CBG and 2CBG, the local density-density
correlation function then naturally vanishes since there is no
double-space occupancy.

In the strong coupling regime [$\gamma \gg \max(1,\sqrt{\tau})$] with
quantum degeneracy ($\tau \ll 1$), the finite-temperature correc-
tions are markedly different in a Lieb-Liniger gas [48] and
the spinor Bose gas [36] with a different exponent. In
Fig. 9 (bottom part) we represent this analytical result next
to numerical results with decreasing temperature for fixed
density of particles. We observe that for $\gamma \gg 10$, the value of
$g^{(2)}$ decreases with $\tau$ and converges to this $T = 0$ analyti-
cal result where the 2CBG is ferromagnetic and does not depend
on $\Omega$. For a high-temperature fermionization ($\gamma^2 \gg \tau \gg 1$), Kheruntsyan
et al. [48] give the first order correction in $\gamma^2/\tau^2$ for $g^{(2)}$ for a
Lieb-Liniger gas. However, the approach of free fermions with
a $1/\gamma$ perturbation is not applicable in the two-component
case; therefore the corrections to the fermionization regime
are unknown. In Fig. 9 (top part) we show next to the
one-component asymptotic curve the decay of $g^{(2)}$ for a fixed
reduced temperature and various relative chemical potentials.
As $\Omega$ reaches 100, the 2CBG polarization is saturated and the
correlator decays like a Lieb-Liniger gas.

VIII. CONCLUSION

In conclusion, we have studied the equilibrium ther-
dodynamic properties of exactly solvable interacting one-
dimensional two-component Bose gas systems as a function
of their external canonical or grand canonical parameters
(either temperature, interaction strength, and total and relative
chemical potential, or temperature, interaction strength, den-
sity of particle, and relative chemical potential). Our method
was based on the solution of thermodynamic Bethe ansatz
equations and yields quantitative predictions which should
be experimentally accessible using cold atomic systems. We
particularly would like to clarify that solving the nonlinear
integrable equations is possible with a very good control of
numerical precision.

Note. Recently a different but equivalent set of equations
was proposed in [56]. While this set of equations is at first
sight more economical, we find and demonstrate here that
the solution of the infinite set of TBA equations is feasible
and practical, robust and reliable. The TBA dressed energies
in Eq. (II) are relatively smooth functions of a real variable,
while the functions of [56] are of a complex variable. The computational effect required by the two methods are thus probably comparable. On the other hand, the fact that results from this alternate method coincide with our results here (and our earlier summary [42]) interestingly confirms that the string hypothesis can be trusted when computing equilibrium thermodynamic results, as expected from general arguments based on the structure of the Bethe equations [57].

ACKNOWLEDGMENTS

The authors would like to thank N. J. van Druten, P. Wicke and A. Klümper for stimulating discussions.

APPENDIX A: THERMODYNAMICS FROM BETHE ANSATZ

We model the system of two-component bosons with SU(2) bosonic fields evolving in a 1D continuum space of length \( L \) with a \( \delta \)-function interaction. The Hamiltonian is then

\[
H = \int_0^L dx \sum_{\alpha=\pm1} \partial_\alpha \Psi^\dagger \partial_\alpha \Psi(x) + c \sum_{\beta,\alpha=\pm1} \Psi^\dagger_\beta \Psi^\dagger_\alpha \Psi_\beta \Psi_\alpha(x)
\]

(\text{A1})

with \( c = \frac{\hbar v}{\Lambda_1} \), \( \Lambda_1 \) the 1D coupling constant and \( m \) the mass of the bosons.

Integrating the string structure \( \lambda_{a,j}^n = \Lambda_a^n + \frac{\pi}{\hbar} (n+1-2j) \), \( j = 1, \ldots, n \) in the scattering equations in (2) and defining \( \epsilon_a(\lambda) = \frac{\Lambda_a^n - \lambda}{\sqrt{\Lambda_a^n - \lambda^2}} \), the scattering equations become

\[
e^{ik_j L} = -\prod_{\ell=1}^N \left[ \frac{k_j - k_j + i \epsilon}{k_j - k_j - i \epsilon} \right] \prod_{n=1}^N \left[ \frac{k_j - \Lambda_a^n - i \epsilon}{k_j - \Lambda_a^n + i \epsilon} \right]
\]

\[
\prod_{p=1}^N \left[ \frac{k_p - \Lambda_a^n + i \epsilon}{k_p - \Lambda_a^n - i \epsilon} \right] = (-1)^m \prod_{\alpha,\beta} \left[ \frac{\epsilon_a(\lambda_m) \epsilon_a(\lambda_m) \epsilon_{a-2m}(\lambda) \cdots \epsilon_{a-2m}(\lambda)}{\epsilon_a(\lambda_m) \epsilon_a(\lambda_m) \epsilon_{a-2m}(\lambda) \cdots \epsilon_{a-2m}(\lambda)} \right], \quad m = n
\]

(\text{A2})

with the notation \( \lambda = \Lambda_a^n - \Lambda_b^m \). In logarithmic form, with \( \frac{1}{i} \ln[\epsilon_a(\lambda)] = \phi_a(\lambda) = -\pi + 2\tan(\frac{\lambda}{\hbar v/2}) \), we have

\[
k_j = 2\pi \frac{I_j}{L} - \frac{1}{L} \sum_{l=1}^N \phi_a(k_j - k_l) + \frac{1}{L} \sum_{n=1}^\infty \sum_{a=1}^N \phi_a(k_j - \Lambda_a^n)
\]

\[
\frac{1}{L} \sum_{p=1}^N \phi_a(k_p - \Lambda_a^n) = \frac{1}{L} 2\pi \frac{I_a}{L} + \frac{1}{L} \sum_{m=1}^\infty \sum_{\beta=1}^N \left[ 2\phi_a(\Lambda_a^n - \Lambda_a^m) + 2\phi_a(\Lambda_a^n - \Lambda_b^m) \cdots \phi_a(\Lambda_a^n - \Lambda_b^m) \right], \quad m = n
\]

(\text{A3})

where \( \{I_j\} \) is a set of \( N \) numbers in \( \mathbb{Z} + \frac{1}{2} \) and \( \{J_a^n\} \) are \( M_a \) sets of \( n \) numbers in \( \mathbb{Z} (\mathbb{Z} + \frac{1}{2}) \) if \( M_a \) is even (odd). These Bethe equations map the sets \( \{I_j\}, \{J_a^n\} \) to the set of rapidities and isospin rapidities, \( \{k_j\} \) and \( \{\Lambda_a^n\} \).

1. Thermodynamic limit

In the limit \( N, L \to \infty \) with the ratio \( \frac{N}{L} \) kept constant, the sets of rapidities (\( \{k_j\} \) and \( \{\Lambda_a^n\} \)) and quantum numbers (\( \{I_j\} \) and \( \{J_a^n\} \)) are replaced by continuous functions of particle root densities in real parameter space:

\[
\rho(x) = \frac{1}{L} \sum_j \delta \left( x - \frac{I_j}{L} \right), \quad \rho(k) = \frac{1}{L} \sum_j \delta \left[ k - k_j \left( \frac{I_j}{L} \right) \right]
\]

\[
\sigma^\beta(y) = \frac{1}{L} \sum_j \delta \left( y - \frac{J_a^m}{L} \right),
\]

\[
\sigma^\alpha(\Lambda') = \frac{1}{L} \sum_j \delta \left[ \Lambda - \Lambda_a^n \left( \frac{J_a^m}{L} \right) \right], \quad \forall n.
\]

(\text{A4})

Hole densities \( \rho_h, \sigma_h^\beta \) are similarly defined from the complementary sets \( \{I'_j\}, \{J'_a^n\} \), and the total root densities are \( \rho_t(k) = \rho_h(k) + \rho_b(k) \) and \( \sigma_t^\alpha(\Lambda) = \sigma_h^\alpha(\Lambda) + \sigma_b^\alpha(\Lambda) \). The thermodynamic limit allows one to replace the discrete sum by an integral over a continuum,

\[
\rho_t(x) = \frac{1}{L} \sum_{I \in \{I_j\}, \{I'_j\}} \delta \left( x - \frac{I}{L} \right) \int_{-\infty}^{+\infty} d\xi \delta(x - \xi) = 1
\]

\[
\sigma_t^\beta(y) = \frac{1}{L} \sum_{J \in \{J_a^n\}, \{J'_a^n\}} \delta \left( y - \frac{J}{L} \right) \int_{-\infty}^{+\infty} d\xi \delta(y - \xi) = 1
\]

(\text{A5})

and the indices of the rapidities by the quantum numbers, \( k_j(L) \) and \( \Lambda_a^n(L) \), become continuous functions \( k(x) \) and \( \Lambda(x) \). An important point of the thermodynamic limit (TL) is the assumption that all the density functions are in \( C^\infty \). However, some sets of \( \{I_j\}, \{J_a^n\} \) that are solutions of Eq. (A2) could provide functions that are not differentiable, for instance, if all the rapidities are grouped in a Fermi-sea-like block. But these solutions play a negligible role in the thermodynamic limit because their weight in the set of all solutions goes to
zero. Physically, they represent the solutions with low entropy. Finally, under the thermodynamic limit Eq. (A3) becomes

\[ k(x) = 2\pi x - \int_{-\infty}^{\infty} \phi_2(k-k')\rho(k')dk' + \sum_{m=1}^{\infty} \int_{-\infty}^{\infty} \phi_m(k-\Lambda)\sigma_m(\Lambda)d\Lambda \]

\[ \int_{-\infty}^{\infty} \phi_n(k-\Lambda)\rho(k)dk \]

\[ = 2\pi y + \sum_{m=1}^{\infty} \int_{-\infty}^{\infty} \sigma_m(\Lambda)d\Lambda \left\{ 2\phi_2(\Lambda-\Lambda') + \cdots + \phi_{2m}(\Lambda-\Lambda'), \quad m = n \right\} \left\{ \phi_{|n-m|}(\Lambda-\Lambda') + \cdots + \phi_{n+m}(\Lambda-\Lambda'), \quad m \neq n. \right\} \]  

(A6)

2. YYT equations

Following the method of Yang and Yang [47], the equilibrium state is determined by minimization of the Gibbs free energy in the grand canonical ensemble. With \( G \) the Gibbs free energy, \( E \) the internal energy, and \( S \) the entropy, we have

\[ \frac{G}{L} = E - TS - \mu_1 N_1 - \mu_2 N_2 \]

\[ \frac{E}{L} = \int_{-\infty}^{\infty} d\rho \left( \rho + \rho_n \right) \ln \left( \rho + \rho_n \right) - \rho \ln \left( \rho \right) - \rho_n \ln \left( \rho_n \right) \]

\[ + \sum_{n=0}^{\infty} \int_{-\infty}^{\infty} d\rho \left( \sigma_n + \sigma_n' \right) \ln \left( \sigma_n + \sigma_n' \right) - \sigma_n \ln \left( \sigma_n \right) - \sigma_n' \ln \left( \sigma_n' \right) \mu_1 n_1 + \mu_2 n_2 = \int_{-\infty}^{\infty} d\Omega \left( \rho - 2 \sum n n^2 \right) + \mu \rho \]

(A7)

with \( L \) the length of our system, \( n_i = \frac{N_i}{N} \) the density of the \( i \)th component particles, and \( \mu = \frac{\mu_1 + \mu_2}{2} \). The condition of equilibrium is then

\[ \frac{\delta G}{\delta \rho} + \delta \rho \frac{\delta G}{\delta \rho_n} + \sum_n \delta \sigma_n \frac{\delta G}{\delta \sigma_n} + \delta \sigma_n' \frac{\delta G}{\delta \sigma_n'} = 0 \]  \quad \left| \rho, \sigma^* \text{solution of BE} \right. \]  

(A8)

from which one derives

\[ \epsilon(k) = k^2 - \mu - \Omega - Ta_2 * \ln (1 + e^{-\varepsilon_2/T}) - \sum_{n=1}^{\infty} T a_n * \ln (1 + e^{-\varepsilon_n/T}) \]

\[ \epsilon_n(k) = 2n \Omega + T a_n * \ln (1 + e^{-\varepsilon_n/T}) + T \sum_{m=1}^{\infty} T_{mn} * \ln (1 + e^{-\varepsilon_n/T}), \quad n = 1, 2, \ldots \]  \quad \]  

(A9)

with

\[ T_{mn}(\Lambda) = \begin{cases} 2a_2(\Lambda) + 2a_4(\Lambda) \cdots a_{2m}(\Lambda), \quad m = n \\ a_{|n-m|}(\Lambda) + 2a_{|n-m|+2}(\Lambda) \cdots a_{n+m}(\Lambda), \quad m \neq n \end{cases} \]  

(A10)

\[ \epsilon(k) = T \ln \left[ \begin{array}{c} \rho_n(k) \\ \rho(k) \end{array} \right] \]  \quad \]  

(A11)

\[ \epsilon_n(k) = T \ln \left[ \begin{array}{c} \sigma_n'(k) \\ \sigma_n(k) \end{array} \right]. \]  \quad \]  

(A12)

The term \( T_{mn} \), which implies a coupling between every \( \epsilon_m(k) \), would severely slow any numerical solving, but following the development of Takahashi [45,46], the system is partially decoupled and this term disappears:

\[ \epsilon(k) = k^2 - \mu - \Omega - T \left\{ a_2 * \ln \left[ 1 + \exp \left( - \frac{\epsilon}{T} \right) \right] \right\}(k) - T \sum_{n=1}^{\infty} \left\{ a_n * \ln \left[ 1 + \exp \left( - \frac{\epsilon_n}{T} \right) \right] \right\}(k) \]  

(A13)

\[ \epsilon_n(k) = \frac{T}{2e} \left\{ f * \left[ \ln \left[ 1 + \exp \left( \frac{\epsilon_n+1}{T} \right) \right] + \ln \left[ 1 + \exp \left( \frac{\epsilon_n-1}{T} \right) \right] \right] \right\}(k), \quad (n \neq 1) \]  

(A14)
\[
\epsilon_1(k) = \frac{T}{2c} \left\{ f * \left[ \ln \left[ 1 + \exp \left( \frac{\epsilon_2}{T} \right) \right] + \ln \left[ 1 + \exp \left( -\frac{\epsilon_2}{T} \right) \right] \right] \right\}(k)
\]  

(A15)

with the convolution notation: \( (f * g)(k) = \int f(k-k')g(k')dk' \), \( a_n(k) = \frac{1}{\pi} \frac{n/2}{\cosh^2(k)} \), \( f(k) = 1/\cosh(k) \).

We can easily calculate the two asymptotic limit similarly to the results for the isotropic spin chain of Takahashi [46]:

\[
\lim_{n \to \infty} \frac{\epsilon_n(k)}{n} = 2\Omega
\]  

(A16)

\[
\lim_{k \to \infty} \epsilon_n(k)(\equiv \epsilon_n^\infty) = 2\Omega n + T \ln \left[ \frac{\left( 1 - \exp \left( -\frac{2\Omega}{T} (n+1) \right) \right)^2}{1 - \exp \left( -\frac{2\Omega}{T} \right)} \right] - \exp \left( -\frac{2\Omega}{T} n \right)
\]  

(A17)

\section*{APPENDIX B: DRESSED ENERGY DERIVATIVES}

The derivatives of \( \epsilon(k) \) and \( \epsilon_n(k) \) are useful for calculation of free-energy derivatives. Differentiating Eqs. (II) and (A17) by \( \nu = \mu, \Omega \), we get

\[
\frac{\partial \epsilon}{\partial \nu}(k) = -1 + \left( a_1 \ast \frac{\partial \epsilon_1}{\partial \nu} \right)(k) + \sum_{n=1}^{\infty} \left( a_n \ast \frac{\partial \epsilon_n}{\partial \nu} \right)(k)
\]

\[
\frac{\partial \epsilon_n}{\partial \nu}(k) = \frac{1}{2c} \left[ f * \left( \frac{\partial \epsilon_{n+1}}{1 + \exp (-\frac{\epsilon_{n+1}}{T})} + \frac{\partial \epsilon_{n-1}}{1 + \exp (-\frac{\epsilon_{n-1}}{T})} \right) \right](k), \quad (n \neq 1)
\]

\[
\frac{\partial \epsilon_1}{\partial \nu}(k) = \frac{1}{2c} \left[ f * \left( \frac{\partial \epsilon_2}{1 + \exp (-\frac{\epsilon_2}{T})} - \frac{\partial \epsilon}{\partial \nu} \right) \right](k)
\]

\[
\lim_{n \to \infty} \frac{\partial \epsilon_n}{\partial \Omega} = 2
\]

\[
\frac{\partial \epsilon_n}{\partial \Omega} = \frac{2 \left\{ 1 - \exp \left[ -\frac{2\Omega}{T} (n+1) \right] \right\}}{1 - \exp \left( -\frac{2\Omega}{T} n \right)} \frac{1 - \exp \left[ -\frac{2\Omega}{T} (n+2) \right]}{1 - \exp \left[ -\frac{2\Omega}{T} \right]}
\]

\[
\times \left\{ \frac{n - n \exp \left( -\frac{2\Omega}{T} (n+2) \right) + (n+2) \exp \left( -\frac{2\Omega}{T} (n+1) \right) - (n+2) \exp \left( -\frac{2\Omega}{T} \right)\right\}
\]

with the derivatives of the asymptotes for \( \nu = \mu \) being identically zero. Differentiating by \( T \) gives

\[
\frac{\partial \epsilon}{\partial T}(k) = \frac{\epsilon(k) - k^2 + \mu + \Omega}{T} + \left( a_1 \ast \frac{\partial \epsilon_1}{\partial T} \right)(k) + \sum_{n=1}^{\infty} \left( a_n \ast \frac{\partial \epsilon_n}{\partial T} \right)(k)
\]

\[
\frac{\partial \epsilon_n}{\partial T}(k) = \frac{\epsilon_n(k)}{T} + \frac{1}{2c} \left[ f * \left( \frac{\partial \epsilon_{n+1}}{1 + \exp (-\frac{\epsilon_{n+1}}{T})} + \frac{\partial \epsilon_{n-1}}{1 + \exp (-\frac{\epsilon_{n-1}}{T})} \right) \right](k), \quad (n \neq 1)
\]

\[
\frac{\partial \epsilon_1}{\partial T}(k) = \frac{\epsilon_1(k)}{T} + \frac{1}{2c} \left[ f * \left( \frac{\partial \epsilon_2}{1 + \exp (-\frac{\epsilon_2}{T})} - \frac{\partial \epsilon_1}{\partial T} \right) \right](k)
\]

\[
\lim_{n \to \infty} \frac{\partial \epsilon_n}{\partial T} = 0
\]

\[
\frac{\partial \epsilon_n^\infty}{\partial T} = \ln \left[ \frac{\left( 1 - \exp \left( -\frac{2\Omega}{T} (n+1) \right) \right)^2}{1 - \exp \left( -\frac{2\Omega}{T} \right)} \right] - e^{-\frac{2\Omega}{T}}
\]

\[
+ \frac{2\Omega}{T} \left[ \exp \left( -\frac{2\Omega}{T} \right) \frac{1 - \exp \left[ -\frac{2\Omega}{T} (n+1) \right]}{1 - \exp \left( -\frac{2\Omega}{T} \right)} \right] - n \exp \left( -\frac{2\Omega}{T} n \right) - 2(n+1) \exp \left( -\frac{2\Omega}{T} (n+1) \right) \frac{1 - \exp \left[ -\frac{2\Omega}{T} (n+1) \right]}{1 - \exp \left( -\frac{2\Omega}{T} \right)}
\]

\[
\left( \frac{1 - \exp \left[ -\frac{2\Omega}{T} (n+1) \right]}{1 - \exp \left( -\frac{2\Omega}{T} \right)} \right)^2 - e^{-\frac{2\Omega}{T}}
\]  

(B2)
And by $c$:

\[
\frac{\partial \varepsilon(k)}{\partial c} = -T \left[ \frac{\partial a_2}{\partial c} \star \ln \left[ 1 + \exp \left( \frac{-\varepsilon}{T} \right) \right] \right](k) - T \sum_{n=1}^{\infty} \left[ \frac{\partial a_n}{\partial c} \star \ln \left[ 1 + \exp \left( \frac{-\varepsilon_n}{T} \right) \right] \right](k) + \left( \frac{a_2 \star \frac{\partial \varepsilon}{\partial c}}{1 + \exp \left( \frac{\varepsilon}{T} \right)} \right)(k) + \sum_{n=1}^{\infty} \left( \frac{a_n \star \frac{\partial \varepsilon_n}{\partial c}}{1 + \exp \left( \frac{\varepsilon_n}{T} \right)} \right)(k),
\]

\[
\frac{\partial \varepsilon_n(k)}{\partial c} = \frac{T}{2c} \left[ \frac{\partial f}{\partial c} - \frac{f}{c} \right] \star \ln \left[ 1 + \exp \left( \frac{\varepsilon_{n+1}}{T} \right) \right] + \frac{T}{1 + \exp \left( \frac{-\varepsilon}{T} \right)} \ln \left[ 1 + \exp \left( \frac{-\varepsilon_n}{T} \right) \right] \right](k) + \frac{1}{2c} \left[ f \left( \frac{\partial \varepsilon_{n+1}}{\partial c} \right) + \frac{\partial \varepsilon_n}{\partial c} \right] \left( \frac{1}{1 + \exp \left( \frac{-\varepsilon_n}{T} \right)} \right) \right](k),(n \neq 1),
\]

\[
\frac{\partial \varepsilon_1(k)}{\partial c} = \frac{T}{2c} \left[ \frac{\partial f}{\partial c} - \frac{f}{c} \right] \star \ln \left[ 1 + \exp \left( \frac{\varepsilon_2}{T} \right) \right] + \frac{T}{1 + \exp \left( \frac{-\varepsilon}{T} \right)} \ln \left[ 1 + \exp \left( \frac{\varepsilon_1}{T} \right) \right] \right](k) + \frac{1}{2c} \left[ f \left( \frac{\partial \varepsilon_2}{\partial c} \right) - \frac{\partial \varepsilon_1}{\partial c} \right] \left( \frac{1}{1 + \exp \left( \frac{-\varepsilon_1}{T} \right)} \right) \right](k),
\]

\[
\lim_{n \to \infty} \frac{\partial \varepsilon_n/\partial c(k)}{n} = 0,
\]

\[
\frac{\partial \varepsilon_\infty}{\partial c(k)} = 0.
\]

**APPENDIX C: COVARIANCE UNDER THE PARAMETER C**

The thermodynamics of the system depend on four parameters: $(c, \mu, \Omega, T)$. Or we can easily deduce from Eq. (II) so that they are covariant under renormalization by $c$, i.e.,

\[
G(c, \mu, \Omega, T) = c^2 G \left( 1, \frac{\mu}{c^2}, \frac{\Omega}{c^2}, \frac{T}{c^2} \right), \quad n_i(c, \mu, \Omega, T) = cn_i \left( 1, \frac{\mu}{c^2}, \frac{\Omega}{c^2}, \frac{T}{c^2} \right), \quad i = 1, 2.
\]

This allows one to reduce our parameter space to $(\mu, \Omega, T)$ and put $c = 1$ by default.
