Hyperpolarized views on the roles of the hyperpolarization-activated channels in neuronal excitability*

Yoav Noam & Tallie Z. Baram

Epilepsy Currents 2010, 10(1), 28-30

*A commentary article, discussing two recently published works:

Regulation of neuronal excitability involves the coordinated function of numerous ion channels. Many ion channels coexist in an individual neuron, and their orchestrated function, influenced by their abundance, subcellular locations, and cellular molecules, modulates channel properties that govern neuronal excitability (Santoro and Baram, 2003; Lai and Jan, 2006; Beck and Yaari, 2008). The role of the hyperpolarization-activated cyclic nucleotide-gated (HCN) channels in regulating neuronal excitability has long been a subject of debate (Santoro and Baram, 2003). These unusual channels open in response to membrane hyperpolarization and mediate the non-inactivating cationic, depolarizing current $I_h$. The depolarizing current conducted by HCN channels drives the membrane potential closer to the action-potential firing threshold; thus, it follows intuitively that these channels may serve an excitatory role. However, by being open at subthreshold membrane potentials, HCN channels also reduce the input resistance of the membrane ($R_{in}$), which results in a shunting inhibitory effect that diminishes the efficiency of incoming EPSPs.

Both upregulation and downregulation of $I_h$ and of HCN channel expression have been reported in several animal models of epilepsy (Chen et al., 2001a; Brewster et al., 2002; Shah et al., 2004; Jung et al., 2007) as well as in human epileptic hippocampus (Bender et al., 2003). However, the complex, apparently contrasting, effects of $I_h$ has impeded further understanding of the physiological consequences of $I_h$ regulation. Two recent studies have addressed directly these issues by studying the contribution of the opposing effects of $I_h$ on dendritic and neuronal excitability. Whereas several previous studies associated downregulation of $I_h$ with increased excitability (Shah et al., 2004; Jung et al., 2007), Dyhrfjeld-Johnsen et al. asked whether upregulation of dendritic $I_h$, which they found after experimental prolonged febrile seizures, could coincide with or even account for hyperexcitability. Importantly, the experimental set-up used by Dyhrfjeld-Johnsen et al. allowed for free fluctuations in resting membrane potential, permitting the study of the depolarizing effect of $I_h$ along with its shunting properties.

The experiments by Dyhrfjeld-Johnsen and colleagues revealed a complex picture: using dendritic recording techniques in hippocampal CA1 pyramidal cells, the investigators observed an upregulated $I_h$ in dendrites of rats that had experienced febrile seizures approximately 4 weeks earlier. In comparison to control animals, this effect was associated with a depolarized membrane potential that was a result of the increased $I_h$, because it could be abolished by pharmacologically blocking the conductance. Injections of current to these neurons resulted in an increased firing rate, compared with control neurons, demonstrating the
HCN channels and neuronal excitability

hyperexcitability of the neurons with augmented dendritic I_{h}. When the depolarizing effects of the augmented I_{h} on membrane potential were blocked (i.e., membrane potential was kept constant), the hyperexcitability was only partially reversed, indicating the involvement of additional, as yet unknown, factors in the modification of neuronal excitability following febrile seizures.

Thus, the results of Dyhrfjeld-Johnsen et al. demonstrated that hippocampal, pyramidal CA1 neurons are hyperexcitable following febrile seizures and that this hyperexcitability was, at least in part, a result of a depolarized membrane potential that was due to upregulated I_{h}. To isolate the potential role of increased I_{h} in febrile seizure-induced hyperexcitability from other influences, the authors then turned to computational models in which the physiological consequences of I_{h} can be studied independently of uncontrolled changes that may occur in vivo. They applied their empirically measured I_{h} values obtained following febrile seizures to three models based on published work, yet allowed membrane potential to fluctuate rather than fixing it at a given value. Under these conditions, the investigators found that the depolarizing effect of I_{h} outweighed its shunting effect in each of the models; in other words, the overall effect of I_{h} was excitatory.

The study by Dyhrfjeld-Johnsen et al. provides an elegant demonstration of how (under certain conditions) I_{h} may play a proexcitatory role and implies that additional channels/conductances may contribute to the hyperexcitability observed in the febrile seizure model. Their findings raise several questions: in which conditions or contexts does I_{h} play an excitatory role? Can the balance between the inhibitory and excitatory effects of I_{h} be dynamically regulated? These questions form the basis for the work by George and colleagues. First, consistent with previous studies, George et al. found that selective pharmacological blocking of I_{h} resulted in the expected hyperpolarized membrane potential in CA1 pyramidal neurons and increased input resistance. A novel and interesting finding involved the biphasic effects of I_{h}: recordings of somatic responses to synaptic stimulation, in the presence or absence of I_{h}, revealed a relationship between the strength of the synaptic stimulus and the function of I_{h}. While the current had a proexcitatory influence on weak synaptic stimuli, it had an inhibitory effect when stronger, yet still subthreshold, stimuli were applied, as measured by reduced peak EPSP. The biphasic relationship between stimulus strength and I_{h} could not be reproduced in a simple computational model in which I_{h} was the only active conductance, because in such a model, I_{h} always exerted an excitatory effect on subthreshold EPSPs (i.e., the depolarizing effect of I_{h} was greater than its shunting properties), indicating that the parameters included in the model were not sufficient to represent the real life neuron. The discrepancy between the experimental observations and the computational prediction was resolved when the authors introduced a new player to their computational model—the subthreshold, slowly activating
potassium conductance, known as the M-current ($I_M$). Not only did the presence of $I_M$ restore the biphasic relationship between stimulus strength and the effect of $I_h$ on excitability, but changes in $I_M$ levels could also shift the crossover point at which $I_h$ turned from excitatory to inhibitory. Thus, the computational data predicted that increased $I_M$ would promote the inhibitory effects of $I_h$ on somatic EPSPs, whereas low levels of $I_M$ would result in a more excitatory $I_h$. These predictions were tested by measuring the effect of $I_h$ on somatic EPSPs in pyramidal CA1 neurons while pharmacologically blocking $I_M$. Indeed, in the absence of $I_M$, $I_h$ had a pure excitatory effect on both weak and strong stimuli.

Both studies reviewed here challenge the traditional notion of a single role for dendritic $I_h$ in regulating neuronal excitability. They suggest the alternative concept that $I_h$ may play either a pro- or anti-excitatory role, depending on physiological conditions, such as the regulation of other active currents and the nature of the neuronal input to the cell (Santoro and Baram, 2003; Dyhrfjeld-Johnsen et al., 2009). While these studies provide experimental support for an important new perspective on $I_h$, they also point out a number of unexplored questions. For example, at the cellular level, HCN channels are regulated in numerous ways that influence not only the magnitude of $I_h$, but also its kinetics, voltage dependence, additional biophysical properties, and location within the neuron. Any of these factors can affect the function of HCN channels. Thus, existing studies have found exquisite transcriptional control of HCN channels (Brewster et al., 2002; Shah et al., 2004; Jung et al., 2007), their heteromerization (Brewster et al., 2005), and their interaction with accessory proteins that influence channel surface expression, subcellular localization, and channel properties (Gravante et al., 2004; Shin et al., 2008; Lewis et al., 2009). The elucidation of these different aspects of HCN channel regulation, especially in relationship to the co-regulation of other ion channels and the physiological context, will further advance the understanding of the function this important class of ion channels. This information will help investigators and clinicians to better understand the pathologies associated with HCN channel dysregulation in the epileptic brain and ultimately will provide targets in the search for better therapies.
