Constraints on dark photon dark matter using data from LIGO’s and Virgo’s third observing run

R. Abbott et al.*

(LIGO Scientific Collaboration, Virgo Collaboration, and KAGRA Collaboration)

(Received 27 May 2021; accepted 8 March 2022; published 31 March 2022)

We present a search for dark photon dark matter that could couple to gravitational-wave interferometers using data from Advanced LIGO and Virgo’s third observing run. To perform this analysis, we use two methods, one based on cross-correlation of the strain channels in the two nearly aligned LIGO detectors, and one that looks for excess power in the strain channels of the LIGO and Virgo detectors. The excess power method optimizes the Fourier transform coherence time as a function of frequency, to account for the expected signal width due to Doppler modulations. We do not find any evidence of dark photon dark matter with a mass between $m_A \sim 10^{-14} - 10^{-11}$ eV/c$^2$, which corresponds to frequencies between 10–2000 Hz, and therefore provide upper limits on the square of the minimum coupling of dark photons to baryons, i.e., $U(1)_B$ dark matter. For the cross-correlation method, the best median constraint on the squared coupling is $\sim 1.31 \times 10^{-47}$ at $m_A \sim 4.2 \times 10^{-13}$ eV/c$^2$; for the other analysis, the best constraint is $\sim 2.4 \times 10^{-47}$ at $m_A \sim 5.7 \times 10^{-13}$ eV/c$^2$. These limits improve upon those obtained in direct dark matter detection experiments by a factor of $\sim 100$ for $m_A \sim [2-4] \times 10^{-13}$ eV/c$^2$, and are, in absolute terms, the most stringent constraint so far in a large mass range $m_A \sim 2 \times 10^{-13} - 8 \times 10^{-12}$ eV/c$^2$.

DOI: 10.1103/PhysRevD.105.063030

I. INTRODUCTION

Dark matter has been known to exist for decades [1], yet its physical nature has remained elusive. Depending on the theory, dark matter could consist of particles with masses as low as $10^{-22}$ eV/c$^2$ [2], or as high as (sub-) solar-mass primordial black holes [3–6]. Furthermore, dark matter clouds could form around black holes that deplete over time and emit gravitational waves [7,8]. Here, we focus on a subset of the “ultralight” dark matter regime, i.e., masses of $O(10^{-14} - 10^{-11})$ eV/c$^2$ [9], in which a variety of dark matter candidates may interact with gravitational-wave interferometers. Scalar, dilaton dark matter could change the mass of the electron and other physical constants, causing oscillations in the Bohr radius of atoms in various components of the interferometer [10]; axions [11] could alter the phase velocities of circularly polarized photons in the laser beams traveling down each arm of the detector [12]; dark photons could couple to baryons in the mirrors, causing an oscillatory force on the detector [13]; tensor bosons could also interact with the interferometer in an analogous way as gravitational waves [14]. Here, we focus on dark photon dark matter whose relic abundance could be induced by the misalignment mechanism [15–17], the tachyonic instability of a scalar field [18–21], or cosmic string network decays [22]. Cosmic strings, in particular, also offer a promising way to probe physics beyond the standard model with gravitational-wave detectors at energies much larger than those attainable by particle accelerators [23], which complements the kind of direct dark matter search we perform here. Independently of the formation mechanism, analyses of gravitational-wave data could make a statement on the existence of dark photons.

A search for dark photons using data from Advanced LIGO/Virgo’s first observing run [13,24] has already been performed, resulting in competitive constraints on the coupling of dark photons to baryons. Furthermore, scalar, dilaton dark matter was searched for recently using data from GEO600 [25], and upper limits were placed on the degree to which scalar dark matter could have altered the electron mass or fine-structure constant [26].

Other experiments that have probed the ultralight dark matter regime include the Eötvös experiment, which aims to find a violation to the equivalence principle of general relativity resulting from a new force acting on test masses in a dark matter field, by looking for a difference in the horizontal accelerations of two different materials using a continuously rotating torsion balance [27,28]; the MICROSCOPE satellite [29], which measures the accelerations of two freely-floating objects in space made of different materials to look for a violation of the equivalence principle and hence a new force [30]; the Axion Dark Matter Experiment (ADMX), which searches for $O(\mu eV/c^2)$ dark matter by trying to induce an axion-to-photon conversion in the presence of a strong magnetic field in a resonant cavity [31]; and the Any Light Particle

*Full author list given at the end of the article.
Search (ALPS), which looks for particles with masses less than $O(\text{meV}/c^2)$ (that could compose dark matter) by subjecting photons to strong magnetic fields in two cavities, separated by an opaque barrier, to cause a transition to an axion and then back to a photon [32]. Ultralight dark matter has also been constrained by observing gravitational waves from depleting boson clouds around black holes [8,33–38], and by analyzing binary mergers, e.g., GW190521, which is consistent with the merger of complex vector boson stars [39].

Compared to the analysis on data from LIGO/Virgo’s first observing run [24], we use two methods, one based on cross-correlation [13], and another that judiciously varies the Fourier Transform coherence time [40,41], to search for dark photons in Advanced LIGO and Virgo data from the third observing run (O3). Additionally, we include the signal induced by the common motion of the mirrors [42]—see Sec. II. Although we do not find any evidence for a dark photon signal, we place stringent upper limits on the degree to which dark photons could have coupled to the baryons in the interferometer.

II. DARK MATTER INTERACTION MODEL

Ultralight dark photon dark matter is expected to cause time-dependent oscillations in the mirrors of the LIGO/Virgo interferometers, which would lead to a differential strain on the detector. We formulate dark photons in an analogous way to ordinary photons: as having a vector potential with an associated dark electric field that causes a quasinimensionoxic force on the mirrors in the interferometers. The Lagrangian $\mathcal{L}$ that characterizes the dark photon coupling to a number current density $J^\mu$ of baryons or baryons minus leptons is

$$\mathcal{L} = -\frac{1}{4\mu_0} F^{\mu\nu} F_{\mu\nu} + \frac{1}{2\mu_0}\left(\frac{m_A c}{\hbar}\right)^2 A^\mu A_\mu - eeJ^\mu A_\mu, \quad (1)$$

where $F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu$ is the electromagnetic field tensor, $\hbar$ is the reduced Planck’s constant, $c$ is the speed of light, $\mu_0$ is the magnetic permeability in vacuum, $m_A$ is the dark photon mass, $A_\mu$ is the four-vector potential of the dark photon, $e$ is the electric charge, and $\epsilon$ is the strength of the particle/dark photon coupling normalized by the electromagnetic coupling constant.$^1$

If the analysis observation time exceeds the signal coherence time, given by Eq. (3) [41], we can write the acceleration of the identical LIGO/Virgo mirrors in the dark photon field as [24]:

$$\ddot{a}(t, \vec{x}) \approx ee \frac{q}{M} \omega \bar{A} \cos(\omega t - \vec{k} \cdot \vec{x} + \phi), \quad (2)$$

where $\omega$, $\vec{k}$, and $\bar{A}$ are the angular frequency, propagation vector, and polarization vector of the dark photon field, $\vec{x}$ is the position of a mirror, $\phi$ is a random phase, and $q$ and $M$ are the charge and the mass of the mirror, respectively. If the dark photon couples to the baryon number, $q$ is the number of protons and neutrons in each mirror. If it couples to the difference between the baryon and lepton numbers, $q$ is the number of neutrons in each mirror. For a fused Silica mirror, $q/M = 5.61 \times 10^{26}$ charges/kg for baryon coupling and $q/M = 2.80 \times 10^{26}$ charges/kg for baryon-lepton coupling. Practically, we cannot distinguish between the two types of coupling, though the baryon-lepton coupling would lead to half the acceleration relative to that of the baryon coupling.

Because we observe for almost one year, significantly longer than the assumed dark photon coherence time, and the dark photons travel with nonrelativistic velocities, we model the signal as a superposition of many plane waves, each with a velocity drawn from a Maxwell-Boltzmann distribution [43]. The superposition of dark photon plane waves with different velocities leads to a frequency variation of the signal [13,41]:

$$\Delta f = \frac{1}{2} \left(\frac{v_0}{c}\right)^2 f_0 \approx 2.94 \times 10^{-7} f_0, \quad (3)$$

where $v_0 \approx 220$ km/s is the velocity at which dark matter orbits the center of our galaxy, i.e., the virial velocity [44], and the frequency $f_0$ is

$$f_0 = \frac{m_A c^2}{2\pi \hbar} \quad (4)$$

Dark photons cause small motions of an interferometer’s mirrors, and lead to an observable effect in two ways. First, the mirrors are well-separated from each other and hence experience slightly different dark photon dark matter phases. Such a phase difference leads to a differential change of the arm length, suppressed by $v_0/c$. A simple relation between dark photon parameters and the effective strain $h_D$ can be written as [13]:

$$\sqrt{\langle h_D^2 \rangle} = C \frac{q}{M} \frac{v_0}{2\pi c^3} \sqrt{\frac{2\rho_\text{DM} ee}{f_0}} \frac{1}{f_0} \approx 6.56 \times 10^{-27} \left(\frac{e}{10^{-22}}\right) \left(\frac{100 \text{ Hz}}{f_0}\right), \quad (5)$$

where $e_0$ is the permittivity of free space, and $C = \sqrt{2}/3$ is a geometrical factor obtained by averaging over all possible dark photon propagation and polarization directions. Equation (5) can be derived by integrating Eq. (2) twice over time, dividing by the arm length of the interferometer, and performing the averages over time and the dark photon polarization and propagation directions.
Second, the common motion of the interferometer mirrors, induced by the dark photon dark matter background, can lead to an observable signal because of the finite travel time of the laser light in the interferometer arms. The light will hit the mirrors at different times during their common motions, and although the common motions do not change the instantaneous arm length, they can lead to a longer roundtrip travel time for the light, equivalent to arm lengthening, and therefore an apparent differential strain \[ h_{\text{D}} \] in Eq. (42). Instead of being suppressed by \( v_0/c \) as shown in Eq. (2), such an effect suffers from a suppression factor of \( (f_0L/c) \), where \( L \) is the arm length of the interferometers. Similarly to Eq. (5), the common motion induces an observable signal with an effective strain \( h_c \) as:

\[
\sqrt{\langle h_c^2 \rangle} \approx \frac{\sqrt{3}}{2} \sqrt{\langle h_D^2 \rangle} \frac{2\pi f_0L}{v_0},
\]

\( \approx 6.58 \times 10^{-26} \left( \frac{\epsilon}{10^{-25}} \right) \). \( (6) \)

\( h_D \) maps to \( h_2 \) in [42], and \( h_c \) is the result of a Taylor expansion of \( h_1 \) in [42]. The interference between the two contributions to the strain averages to zero over time, which indicates that the total effective strain can be written as \( \langle h_{\text{total}}^2 \rangle = \langle h_D^2 \rangle + \langle h_C^2 \rangle \).

### III. SEARCH METHOD

#### A. Cross-correlation

Cross-correlation has been widely used in gravitational-wave searches [45–47], but is employed differently here. Because we are interested in ultralight dark matter, the coherence length of a dark photon signal, given by Eq. (2) in [41], is always much larger than the separation between earth-based detectors [19]. Therefore, the interferometers should experience almost the same dark photon dark matter field, and the signals at any two detectors are highly correlated [19].

Because the dark photon signal is quasimonochromatic, we analyze the frequency domain by discrete Fourier transforming the strain time series. Given a total coincident observation time, \( T_{\text{obs}} \), for two detectors, we divide the time series into \( N_{\text{FFT}} \) smaller segments, with durations \( T_{\text{FFT}} \), i.e., \( T_{\text{obs}} = N_{\text{FFT}} T_{\text{FFT}} \). For the \( j \)th time segment, \( j \)th frequency bin, and interferometer \( k \) (1 or 2), we label the complex discrete Fourier transform coefficients as \( z_{k,ij} \). The one-sided power spectral densities (PSDs) of interferometer 1(2) can be estimated by taking a (bias-corrected) running median of the raw noise powers \( P_{k,ij} \) from 50 neighboring frequency bins: \( \text{PSD}_{k,ij} = 2P_{k,ij}/T_{\text{FFT}} \).

The cross-correlated signal strength is

\[
S_j = \frac{1}{N_{\text{FFT}}} \sum_{i=1}^{N_{\text{FFT}}} z_{1,ij}^* z_{2,ij}^* \frac{P_{1,ij} P_{2,ij}}{P_{1,ij} P_{2,ij}},
\]

where \( \ast \) is the complex conjugate, and the variance is

\[
\sigma_j^2 = \frac{1}{N_{\text{FFT}}} \left( \frac{1}{2} \right) \frac{1}{N_{\text{FFT}}} \cdot \frac{P_{1,ij} P_{2,ij}}{N_{\text{FFT}}},
\]

where \( \langle \ldots \rangle_{N_{\text{FFT}}} \) is the average over \( N_{\text{FFT}} \) time segments. Therefore, the signal-to-noise ratio (SNR) is

\[
\text{SNR}_j = \frac{S_j}{\sigma_j}.
\]

In Gaussian noise without a signal, \( \text{SNR}_j \) has zero mean and unit variance. The presence of a signal would lead to a nonzero offset in the mean SNR proportional to \( \epsilon^2 \) [see Eqs. (5)–(6)]. We note that we will include the overlap reduction function (ORF) in our upper limit calculation, which accounts for the relative orientation and overlap of two detectors and the responses of the detectors to a signal. As indicated in [13], the ORF is constant \( (\sim 0.9) \) for the LIGO Hanford (H1) and LIGO Livingston (L1) detectors because the dark photon coherence length always exceeds the detector separation.

Here, we analyze only time segments satisfying standard data quality requirements used in gravitational-wave searches (see Sec. IV), and further restrict to contiguous, coincident intervals of good data spanning the fast Fourier transform coherence time. As in the analysis performed using data from the first observing run (O1) [24], we set \( T_{\text{FFT}} = 1800 \) s, a pragmatic compromise between recovering signal power at high frequencies with shorter-than-optimal coherence times, and reducing noise contamination at low frequencies for longer-than-optimal coherence times. An important constraint at low frequencies is that requiring longer (contiguous) coherence times necessarily reduces total available livetime, especially given the need for coincident H1 and L1 data. In total, we analyze 7539 pairs of 1800-second coincident time segments from H1 and L1.

#### B. BSD analysis

In addition to cross-correlation, we employ an independent method [41] to search for dark photon dark matter. The method relies on band sampled data (BSD) structures, which store the detector’s downsampled strain data as a reduced analytic signal [40] in 10-Hz/1-month chunks. In each 10-Hz band, we change the fast Fourier transform coherence time [40] based on the expected Maxwell-Boltzmann frequency spread of dark photons, Eq. (3). Although this frequency spread is given as a function of \( v_0 \), we instead use the escape velocity from the galaxy, \( v_{\text{esc}} \approx 540 \) km/s [44], to determine the maximum allowed \( T_{\text{FFT}} \), \( T_{\text{FFT,max}} \), by requiring that the frequency spread be contained in one frequency bin in \( T_{\text{FFT,max}} \).
IV. DATA

We use data from the third observing run (O3) of the Advanced LIGO [51] and Virgo [52] gravitational-wave detectors between 10–2000 Hz. O3 lasted from 2019 April 1 to 2020 March 27, with a one-month pause in data collection in October 2019. The three detectors’ datasets, H1, L1, and Virgo (V1), had duty factors of ~76%, ~77%, and ~76%, respectively, during O3.

In the event of a detection, calibration uncertainties would limit our ability to provide robust estimates of the coupling of dark matter to the interferometers. Even without a detection, these uncertainties affect the estimated instruments’ sensitivities and inferred upper limits. The uncertainties vary over the course of a run but do not change by large values, so we do not consider time-dependent calibration uncertainties here [53].

For the LIGO O3 data set, the analyses use the “C01” calibration, which has estimated maximum amplitude and phase uncertainties of ~7% and ~4 deg, respectively [53]. Because of the presence of a large number of noise artifacts, gating [54,55] has also been applied to LIGO data. This procedure applies an inverse Tukey window to LIGO data at times when the root-mean-square value of the whitened strain channel in the 25–50 Hz band or 70–110 Hz band exceeds a certain threshold. The improvements from gating are significant, as seen in stochastic and continuous gravitational-wave analyses in O3 [46]. For the Virgo O3 dataset, we use the “V0” calibration with estimated maximum amplitude and phase uncertainties of 5% and 2 deg, respectively.

V. RESULTS

A. Cross-correlation

The output of the cross-correlation analysis is a value of the SNR in every frequency bin analyzed. At this point, we remove frequency bins with noise artifacts, i.e., bins within 0.056 Hz of known noise lines [56]. To further estimate the non-Gaussian background from artifacts, control samples are constructed using frequency lags, i.e., examining the correlations among a set of offset bins. We apply ten lags of the frequency bin offsets, i.e., (−50, −40, ..., −10, +10, ..., +50). If any frequency bin in the control sample has a $|\text{Re}(\text{SNR})|$ or $|\text{Im}(\text{SNR})|$ larger than 4.0 within 0.1 Hz of the outlier, the outlier is vetoed as contaminated by spectral leakage from a nearby non-Gaussian artifact. We choose a band of 0.1 Hz because within that band, spectral leakage causes non-physical correlated amplitudes and phases. Furthermore, ten lags allow us to compare frequency bins that are not too far from each other to construct an estimation of the noise in the chosen frequency bin.

After removing these instrumental artifacts, we look for frequency bins with $\text{Re}(\text{SNR}) < -5.8$, which corresponds to an overall ~1% false alarm probability after including the trial factor in Gaussian noise, and is negative because...
artifacts occur because when there are strong lines at instrumental noise or artifacts in the peakmap. Peakmap number of coincident candidates in Fig. 7. We show distributions of CR in the Hanford and Livingston in L1 or H1 because Virgo is less sensitive than LIGO. We reject candidates whose critical ratios in V1 are higher than those in each detector. In the HV and LV baselines, we remove candidates whose critical ratios differ by more than a factor of two because the sensitivity of each interferometer is comparable, so we do not expect a dark photon signal to appear with vastly different critical ratios near an outlier at 1498.76 Hz, where a family of combs is present in both the H1 and L1 detectors.

Finally, as a cross-check, between [5.0, 5.8] for |Re(SNR)| or |Im(SNR)|, we find four nonvetoed outliers, which are shown in Table I. The number of outliers is consistent with the Gaussian noise expectation of 4.1. We consider the absolute value of the real and imaginary components of the SNR because we are checking consistency with the expected number of outliers in Gaussian noise, which does not depend on the sign of the SNR. We show the distribution of the real and imaginary parts of the SNR in the Appendix.

### B. BSD analysis

Before selecting candidates, we remove any frequencies that fall within one frequency bin of known noise lines from each detector’s data. We subsequently require coincident candidates between two or more detectors to be within one frequency bin of each other. At this stage, our analyses of the Hanford-Livingston (HL), Hanford-Virgo (HV), and the Livingston-Virgo (LV) baselines return 5801, 5628, and 5592 candidates, respectively.

In all baselines, we veto coincident candidates if one of the candidates’ critical ratios is less than five or one of the candidates’ frequencies is too close, i.e., within 5 bins, to the edges of the 10 Hz-band analyzed. The latter veto is necessary because the construction of the BSDs introduces artifacts in some bands at the edges. For the HL baseline, we remove candidates whose critical ratios differ by more than a factor of two because the sensitivity of each interferometer is comparable, so we do not expect a dark photon signal to appear with vastly different critical ratios near an outlier at 1498.76 Hz, where a family of combs is present in both the H1 and L1 detectors.

We are then left with eleven surviving candidates across the three baselines, given in Table II, that are all due to instrumental noise or artifacts in the peakmap. Peakmap artifacts occur because when there are strong lines at particular frequencies, we tend to select peaks that correspond to those lines. This causes a “depletion” of peaks nearby, and thus, a candidate could result because the level of the noise in the projected peakmap is lower on one side than on the other. No candidate has been found to be coincident in all three interferometers. These surviving candidates do not overlap with the list of known lines used in this search, although line artifacts or/and combs regions are clearly visible when using a different resolution to construct the spectra.

### C. Upper limits

Finding no evidence of a signal, in Fig. 3 we place 95% confidence-level upper limits on the square of the minimum detectable dark photon/baryon coupling, $U(1)_B$, using the HL baseline. The cross-correlation limits are 95% confidence-level upper limits on the square of the minimum detectable dark photon/baryon coupling, $U(1)_B$, using the HL baseline. The cross-correlation limits are...
shown in red for every 0.556-mHz bin, while the BSD limits are given in black with cyan 1σ shading in frequency bins in which coincident candidates were found. To calculate these limits, we employ the Feldman-Cousins [59] approach, in which we assume that both CR and SNR follow Gaussian distributions, and map the measured detection statistics to “inferred” positive-definite statistics based on the upper value of Table 10 of [59] at 95% confidence. As shown in [5], this approach produces consistent limits with respect to those that would be obtained by injecting simulated signals. With our estimates of the noise power spectral density and $T_{\text{FFT}}$, we can translate the inferred SNR and CR at each frequency to the corresponding signal amplitude using Eq. (9) in [13] and Eq. (30) in [41], respectively. This amplitude is then converted to a coupling strength using Eq. (5), and adjusted for the common mode motion effect [42].

The limits from the cross-correlation analysis are more stringent than those from the BSD method because the former employs the phase information of the signal, while the latter only looks at power. Furthermore, though the choice of $T_{\text{FFT}}$ is “optimal” in the BSD method, it is still shorter than that used by cross correlation by as much as a factor of six above $\sim 330$ Hz, and the definition of optimal depends on whether we consider the escape or virial velocity of dark matter as responsible for the frequency

| TABLE II. Outliers returned by the BSD analysis. The frequency resolution of each outlier is $1/T_{\text{FFT}}$. We have determined the origin of all outliers to be from instrumental lines or peakmap artifacts. No outlier was found to be in triple coincidence. A list of unidentified lines can be found in [58]. |  |
|---|---|---|---|---|
| Frequency (Hz) | Average CR | $T_{\text{FFT}}$ (s) | Baseline | Source |
| 15.9000 | 5.29 | 44762 | HL | Unknown line in L |
| 17.8000 | 28.93 | 44762 | LV | Unidentified line in L (17.8 Hz) |

| 1982.91 | 6.34 | 450 | HL | Noisy violin resonance regions |

FIG. 3. Upper limits derived using a Feldman-Cousins approach for both searches on dark photon/baryon coupling, $U(1)_B$. The limits from each method are comparable, noting that the BSD-based analysis takes an optimally chosen $T_{\text{FFT}}$ and can observe for twice as long than the cross-correlation method can. We plot for comparison upper limits from MICROSCOPE given in [30], though other weaker limits exist [60–62], that have been converted from the coupling constant to gravity, $\alpha$, to $\epsilon^2$, using the equation below Fig. 3 in [63], and from the Eöt-Wash torsion balance experiment [28]. To produce limits on dark photon/baryon-lepton coupling, $U(1)_{B-L}$, our limits should be multiplied by four. See Supplemental Material [50].
VI. CONCLUSIONS

We have presented strong constraints on the coupling strength of dark photon dark matter to baryons by using data from LIGO’s and Virgo’s third observing run. In the mass range $m_A \sim [2-4] \times 10^{-13}$ eV/c$^2$, we improve upon previous limits derived using data from the first observing run of LIGO [24] by a factor of $\sim 100$ in the square of the coupling strength of dark photons to baryons. This improvement is due to more sensitive detectors and to accounting for the finite light travel time [42]. Additionally, our limits surpass those of existing dark matter experiments, such as the Eötvös torsion balance and MICROSCOPE, by orders of magnitude in certain frequency bands, and support new ways to use gravitational-wave detectors as direct probes of the existence of ultralight dark matter. As the sensitivities of current ground-based gravitational-wave detectors improve, and third generation detectors, such as Cosmic Explorer [64] and Einstein Telescope [65], come online, we will dig even more deeply into the noise. Furthermore, once future-generation space-based detectors, such as DECIGO [66], LISA [67], and TianQin [68], are operational, we will probe dark photon couplings at masses as low as $m_A \sim 10^{-18}$ eV/c$^2$.

This work was supported by MEXT, JSPS Leading-edge Research Infrastructure Program, JSPS Grant-in-Aid for Specially Promoted Research 26000005, JSPS Grant-in-Aid for Scientific Research on Innovative Areas 2905: No. JP17H06358, No. JP17H06361 and No. JP17H06364, JSPS Core-to-Core Program A Advanced Research Networks, JSPS Grant-in-Aid for Scientific Research (S) No. 17H06133, the joint research program of the Institute for Cosmic Ray Research, University of Tokyo, National Research Foundation (NRF) and Computing Infrastructure Project of KISTI-GSDC in Korea, Academia Sinica (AS), AS Grid Center (ASGC) and the Ministry of Science and Technology (MoST) in Taiwan under grants including AS-CDA-105-M06, Advanced Technology Center (ATC) of NAOJ, and Mechanical Engineering Center of KEK.

APPENDIX: DISTRIBUTION OF DETECTION STATISTICS

We provide here more details on our detection statistics for both methods. When we calculate upper limits, we assume that these statistics follow Gaussian distributions,
which is actually true only in clean bands. But, because we showed the Feldman-Cousins approach to be robust toward noise disturbances in [41], we are confident that the limits are reflective of what we would have obtained if we performed software injections.

For the cross-correlation search, the distributions of the real and imaginary parts of the SNR are shown in Fig. 4 after vetoing frequency bins within 0.056 Hz of the known noise lines [56] and after vetoing the instrumental artifacts as described in the main text above.

We show the distributions of the CR in Hanford (Fig. 5) and Livingston (Fig. 6), over all frequency bins between 10–2000 Hz. We also overlay a Gaussian on the plot to show the extent to which the distributions differ from a Gaussian distribution. In both detectors, the number of frequency bins whose CRs deviate from Gaussianity is of $O(10^2)$, which is a small fraction of the total number of bins analyzed.

We also include a plot to characterize the coincident candidates between Hanford and Livingston that are

FIG. 4. Distribution of the real (top) and imaginary (bottom) parts of the SNR in the cross-correlation search, with those corresponding to on-source (with zero lag) results in magenta, background (with frequency lags) in black and the ideal Gaussian distribution in green.

FIG. 5. Histogram of critical ratios in all frequency bins in the Hanford detector, with a Gaussian (in red) overlayed.

FIG. 6. Histogram of critical ratios in all frequency bins in the Livingston detector, with a Gaussian (in red) overlayed.

FIG. 7. Histogram of coincident critical ratios, after our selection of candidates in each 10-Hz frequency band. We performed the coincidences between the candidates returned after analyzing Hanford and Livingston data.
selected in our search. Figure 7 shows a histogram of all the coincident candidates’ critical ratios that we select, as well as a black line that indicates the threshold on the critical ratio that we impose, equal to 5. We can see that very few candidates are coincident relative to the number of candidates plotted in Figs. 5 and 6, and that the total number of coincident candidates that are subject to further study is of $O(1000)$.
