Type I IFN and TNFα cross-regulation in immune-mediated inflammatory disease: basic concepts and clinical relevance

Tineke Cantaert, Dominique Baeten, Paul P Tak* and Lisa GM van Baarsen

Abstract
A cross-regulation between type I IFN and TNFα has been proposed recently, where both cytokines are hypothesized to counteract each other. According to this model, different autoimmune diseases can be viewed as disequilibrium between both cytokines. As this model may have important clinical implications, the present review summarizes and discusses the currently available clinical evidence arguing for or against the proposed cross-regulation between TNFα and type I IFN. In addition, we review how this cross-regulation works at the cellular and molecular levels. Finally, we discuss the clinical relevance of this proposed cross-regulation for biological therapies such as type I IFN or anti-TNFα treatment.

Type I IFN and TNFα: cytokines with pleiotropic functions
The family of type I IFN consists of multiple subtypes of IFNα, a single IFNβ and some less characterized family members, such as IFNε, IFNκ and IFNω. The difference in biological function between the multiple subtypes of type I IFN is unclear, especially since the induced genes downstream of the different types of IFN (the IFN response program) are highly similar between, for example, IFNα and IFNβ. In peripheral blood, plasmacytoid dendritic cells (pDC) are the main producers of type I IFN. All nucleated cells, however, can produce type I IFN upon activation by, for example, viral infections that trigger cytoplasmic nucleic acid sensors such as TLR-7 and MDA-5.

Binding of type I IFNs to their cognate receptor (a heterodimer of IFNAR1 and IFNAR2) leads to the phosphorylation of signal transducers and activators of transcription (STATs) and transcription of IFN response genes. This results in resistance to viral replication, enhanced MHC class I expression and differentiation of monocytes, all of which contribute to clear infection. Besides an essential role in the host antiviral state, type I IFN has immunoregulatory functions by affecting cell proliferation and differentiation and by inducing anti-inflammatory responses. Considering these important functions of type I IFN in normal homeostasis as well as host response, an aberrant function in type I IFN immunity may contribute to autoimmunity and chronic inflammation. This is illustrated by the observation that melanoma patients treated with IFNα2β developed clinical and serological signs of autoimmunity [1] and that patients with a trisomy of chromosome 9, which contains the type I IFN genes, develop high IFN levels and lupus-like disease [2].

TNFα is a pivotal pro-inflammatory cytokine produced by macrophages, activated T cells, natural killer cells and mast cells. Also non-immune, stromal cells are able to produce significant amounts of TNFα. TNFα is produced as a 26 kDa transmembrane protein, which can be cleaved by TNFα converting enzyme to form the 17 kDa soluble form. Upon binding to TNFR1 (which is constitutively expressed on most cell types) or TNFR2 (which is expressed on immune cells, endothelial cells and fibroblasts), TNFα activates the mitogen-activated protein kinase and NF-κB signaling pathways [3] – which in turn can lead to an amplification of the proinflammatory response by increased production of chemokines and cytokines, including TNFα itself. Endothelial cells respond to TNFα by expressing adhesion molecules to facilitate trafficking of immune cells to the inflamed tissue. Macrophages and neutrophils are attracted to the site, increase their cytokine production, and enhance phagocytic capacities. Taken together, TNFα initiates and orchestrates different mechanisms that lead to an effective immune response in the case of infection.

Besides its role in host defense, however, TNFα is recognized to play a key role in many immune-mediated inflammatory diseases (IMIDs), such as rheumatoid
arthritis (RA), spondyloarthritis, psoriasis, and inflammatory bowel disease [4]. Accordingly, anti-TNFα treatment is very effective in these conditions. Interestingly, a recent animal study showed that the primary cell target of TNF in chronic inflammatory joint and intestinal diseases is mesenchymal cells [5], a cell type that can produce large amounts of type I IFN.

**Cross-regulation of TNFα and type I IFN: the hypothesis**

The relative contribution of TNFα and type I IFN to different types of autoimmunity and inflammatory disease is not well understood. An even more complex and intriguing picture emerged from the recently proposed hypothesis of an intimate interplay between both pleiotropic cytokines [6,7]. This hypothesis proposes that, similarly to Th1 and Th2 cytokines in T-cell biology, both cytokines can be regarded as opposite vectors in many innate immune responses. If both vectors are in balance, the sum normally yields an equilibrium point allowing protective immunity. Disturbance of this balance beyond a certain threshold may contribute to pathological conditions such as autoimmunity and inflammation (Figure 1a). A shift towards the TNFα arm may create a permissive environment for TNF-mediated autoimmunity in rheumatoid arthritis (RA). In contrast, when the type I IFN arm prevails, IFN-driven autoimmunity as observed in systemic lupus erythematosus (SLE) may occur. (b) An alternative hypothesis: in homeostatic conditions, type I IFN and TNFα are influencing each other’s levels but this balance is lost in a pathological condition. (c) An alternative hypothesis: type I IFN plays an important role in the initiation of autoimmunity, while the role of TNFα increases during the secondary inflammatory phase.

**Figure 1. Cross-regulation between type I IFN and TNFα.** (a) The original hypothesis proposes that both cytokines can be regarded as opposite vectors. Whereas the sum of both vectors normally yields an equilibrium point allowing protective immunity, disturbance of this balance beyond a certain threshold may contribute to a pathological state promoting autoimmunity, allergy, or inflammation. A shift towards the TNFα arm may create a permissive environment for TNF-mediated autoimmunity in rheumatoid arthritis (RA). In contrast, when the type I IFN arm prevails, IFN-driven autoimmunity as observed in systemic lupus erythematosus (SLE) may occur. (b) An alternative hypothesis: in homeostatic conditions, type I IFN and TNFα are influencing each other’s levels but this balance is lost in a pathological condition. (c) An alternative hypothesis: type I IFN plays an important role in the initiation of autoimmunity, while the role of TNFα increases during the secondary inflammatory phase.
overexpression of IFNα-regulated genes in their peripheral blood mononuclear cell (PBMC) compartment compared with untreated control patients [6,8]. In addition, they showed that IFNα production by virally stimulated pDC is inhibited by TNFα through induction of maturation [8]. As this conceptual model may have important clinical implications for treatment with TNFα blockers or with type 1 IFN, the present review summarizes and discusses the currently available clinical evidence for the proposed cross-regulation between TNFα and type 1 IFN at the cellular level as well as in experimental models and in IMID patients. A summary of all studies cited is presented in Tables 1 and 2.

Cross-regulation of TNFα and type I IFN at the cellular level
At the cellular level, the hypothesis of cross-regulation between TNFα and type I IFN is based on the observation that TNFα inhibits the generation of pDC as well as the secretion of type I IFN by immature pDC upon viral triggering [8]. Incubation of influenza-virus activated pDC with TNFα inhibited the IFNα production by 40%, which was due to maturation of the pDC by TNFα rather than a direct inhibition or cross-regulation. In vitro culture of healthy PBMCs with the soluble TNFα receptor etanercept resulted in a dose-dependent increase in the expression of IFNα and IFNα-inducible genes [9]. These studies specifically focused on IFNα and not on IFNβ, but similar genes are induced by IFNβ. In contrast with these findings in PBMCs, studies on human fibroblasts indicated that stimulation with TNFα induced an approximately 16-fold increase in the steady-state level of IFNβ mRNA [10]. Moreover, it has been shown more recently that TNFα induces a type I IFN response program in macrophages through IFN regulatory factor-1 activation, leading to an IFNβ-mediated autocrine loop [11]. The TNFα canonical pathway and the IFNβ pathway may thereby synergize in the expression of downstream response genes. Taken together, these data suggest that the suppressive effect versus stimulating effect of TNFα on the synthesis of type I IFN is not universal but, rather, is cell-type dependent.

The opposite question related to the presumed cross-regulation is whether type I IFN suppresses TNFα production. Indeed, several studies have shown suppressive effects of type I IFN. Stimulation of peripheral blood cells with IFNβ decreases the production of TNFα [12,13]. In addition, IFNβ augmented dexamethasone-mediated suppression of TNFα in a human monocytic cell line [14]. A study on human macrophages indicated that IFNα can suppress TNFα production after immune complex, Fc receptor or Toll-like receptor stimulation by induction and activation of Axl, a receptor tyrosine kinase that induces the expression of a transcriptional repressor of the TNFα promoter [15]. Moreover, IFNβ can induce the expression of tristetraprolin, an RNA-binding protein that destabilized the mRNA of pro-inflammatory cytokines including TNFα [16]. Accordingly, IFN-induced tristetraprolin limits lipopolysaccharide (LPS)-induced expression of several proinflammatory cytokines, including TNFα, by macrophages.

Of interest, the inhibitory effect of IFNβ on TNFα production by human monocytes was shown to be stimulus dependent. IFNβ diminishes TNFα production in T-cell contact-activated monocytes, while IFNβ enhances TNFα production in LPS-activated monocytes [17]. Another study showed that direct stimulation of murine macrophages with IFNβ does not suppress TNFα but, on the contrary, induces a fourfold upregulation of TNFα mRNA expression [18]. Whether the same holds true for IFNα awaits further investigation. Besides these direct effects, low constitutive expression of type I IFN in many cell types contributes to boost the responsiveness towards other cytokines. This phenomenon – called cross-priming – implicates that previous exposure to low doses of the pleiotropic type I IFN enhances subsequent response to proinflammatory cytokines such as TNFα [19]. Taken together, these cellular studies yield conflicting results going from cross-priming to cross-regulation of TNFα production by type I IFN. This may be partially due to differences in experimental settings mimicking homeostasis versus inflammatory conditions.

Counterbalance of TNFα and type I IFN in experimental models of inflammation and autoimmunity
The cellular studies indicated that the proposed cross-regulation of type I IFN and TNFα may depend on both cell type and inflammatory conditions, thereby emphasizing the need for additional information on this cross-regulation in vivo in the context of tissue inflammation and autoimmunity. The NZB/W mouse, a model for SLE, bears a genetic defect in the TNFα gene that leads to reduced levels of TNFα [20]. These mice develop antinuclear antibodies and nephritis. In accordance, treatment of the mice with TNFα resulted in attenuation of the disease.

An IFNα signature has been characterized in the splenic mononuclear cells of pre-autoimmune NZB/W mice that is not observed in BALB/c control mice [21]. Also, whereas IFNα serum levels are undetectable in both Balb/c control mice and NZB/W mice under homeostatic conditions, NZB/W mice but not Balb/c control mice produced IFNα after poly I:C stimulation [22]. On the other hand, IFNβ KO mice, which have an increased susceptibility to experimental autoimmune encephalomyelitis, display extensive microglia activation and TNFα

production in the effector phase of the disease [23]. Macrophages isolated from these mice after experimental autoimmune encephalomyelitis induction produced increased amounts of TNFα after stimulation with LPS and IFNγ, compared with wild-type controls [23]. In addition, these IFNβ KO mice are also more susceptible to collagen-induced arthritis and develop an exacerbated disease compared with control mice, with a greater production of TNFα [24]. Of interest, mice lacking the receptor for type I IFN (IFNAR1) or IFNβ are protected against TNFα-induced lethal shock [25] — showing that the absence of type I IFN signaling may not only impact TNFα production, but also the outcome of the TNFα-induced inflammation.

These observations also raise the reverse question: does increased type I IFN signaling downregulate TNFα production and/or TNF-induced inflammation? IFNβ treatment has a significant therapeutic effect in collagen-induced arthritis in mice and rhesus monkeys as well as in adjuvant arthritis in rats [26-28]. In these models, IFNβ was shown to have an inhibitory effect on the production of TNFα by LPS-stimulated macrophages [26]. Indirect upregulation of type I IFN also showed beneficial effects in mouse models of arthritis [29,30]. In addition, mice treated with IFNβ had a 50% lowered expression of TNFα in the synovial tissue [28].

Taken together, these animal models demonstrate the presence and functionality of the cross-regulation between TNFα and type I IFN, but also indicate that this cross-regulation occurs mainly in a context-dependent manner during inflammatory conditions (Table 2). These observations in turn raise the question of whether and to what extent the inflammatory conditions seen in these experimental models are relevant for human IMIDs.

**Cross-regulation of TNFα and type I IFN in immune-mediated inflammatory diseases**

Upregulation of type I IFN-response genes has now been observed in peripheral blood cells and/or target tissue in many different IMIDs — for example, RA [31], SLE [32], systemic scleroderma [33], multiple sclerosis (MS) [34,35], psoriasis [36,37], Sjögren’s syndrome (SS) [38], dermatomyositis [39] and type 1 diabetes [40]. These findings suggest that an activated type I IFN gene expression program may be a common denominator in chronic inflammatory diseases in general. If cross-regulation is present and effective, this activated type I IFN response program should lead to a repressed TNFα profile. Most of these diseases, however, also have an elevated expression of TNFα both systemically and locally in the target tissues. For example, upregulation of both TNFα and type I IFN has been shown in lesional skin in psoriasis [37] as well as in synovial tissues of RA [41] and juvenile idiopathic arthritis patients [42]. The question therefore arises of whether cross-regulation might be insufficient in specific pathological conditions.

The relative balance between IFNα and TNFα has been studied in more detail in juvenile dermatomyositis. By measuring serum IFNα activity, higher serum IFNα levels were shown to be associated with the presence of the TNFα-308 promoter polymorphism [43]. This polymorphism leads to increased production of TNFα in 50% of the carriers of the minor allele [44]. In early untreated patients, serum IFNα activity and TNFα are positively correlated. As the disease progresses, however, serum IFNα activity levels go down while TNFα levels remain stable [43]. This observation indicates that type I IFN might be more important in the earliest phases of the autoimmune phase of disease, while TNFα plays a more prominent role in the secondary effector phase of the disease (Figure 1b). Collectively, the relationship between both cytokines is influenced by timing and disease progression.

The relationship between type I IFN and TNFα also appears to be complex in SLE. Patients with SLE display a strong type I IFN signature but also systemic overexpression of TNFα. Moreover, serum TNFα levels correlate with disease activity [45]. Recently, serum levels of both TNFα and IFNα were measured by ELISA in 171 SLE patients. The patients showed elevated levels of both cytokines, and the correlation between both was highly significant [46]. Another study, however, indicated that clustering of SLE patients according to serum IFNα activity and TNFα levels resulted in three groups: a group in which IFNα levels were much higher than TNFα levels, a group in which IFNα and TNFα levels were correlated, and a group in which TNFα levels were much higher than IFNα levels [47]. The latter group had a weaker association with PTPN22 SNPs than the former two groups. This study suggests that the relative balance between both cytokines may also be heterogeneous within one single disease.

This heterogeneity was also confirmed in MS, where a subgroup of patients displayed increased expression levels of type I IFN response genes in the peripheral blood [34]. The extent of this type I IFN signature before treatment was inversely associated with the biological and clinical response to IFNβ treatment [35, 48]. Elevated TNFα levels have been detected in the peripheral blood and brain lesions of MS patients, and correlated with disease activity [49], but it remains unknown whether there is a relationship with the type I IFN signature.

In RA, TNFα is overexpressed in the primary target tissue of the disease – the synovial membrane [50]. In addition, the expression of IFNβ as well as the number of IFNα-expressing and IFNβ-expressing pDC is significantly elevated in RA synovial tissue compared with synovial tissues from patients with osteoarthritis or reactive arthritis [41]. A similar picture emerges from peripheral blood, as about one-half of the RA patient population shows elevated expression levels of type I IFN response genes compared with healthy controls [31]. In the other half of the patients, the type I IFN response gene expression profile is similar to that of healthy controls. Of interest, the peripheral blood IFN gene signature can already be observed in the preclinical phase of the disease [51]. The clinical significance of this elevated type I IFN expression profile in blood is still unknown, as there is no difference in patient characteristics or disease severity between patients with elevated or normal expression levels of type I IFN response genes. Thus, in RA both cytokines appear to be elevated systemically as well as in the target tissue.

Together, these studies in different IMIDs clearly indicate that there is no straightforward balance between the levels of type I IFN and TNFα, and that factors such as the specific type of IMID, the disease phase, and patient-specific factors may contribute to create a complex picture. One also has to consider that it is not completely clear how the absolute levels of these cytokines relate to their functional activity and role in disease pathogenesis.

Cross-regulation of TNFα and type I IFN during targeted treatment

Targeted therapies aimed at regulating cytokine activity provide an experimental approach to study cross-regulation between TNFα and type I IFN in patients. In fact, the concept of TNFα/type I IFN cross-regulation proposed by Banchereau and colleagues was based on the observation that juvenile chronic arthritis patients treated with infliximab (anti-TNFα monoclonal antibody) displayed increased transcription of IFNα-regulated genes compared with untreated patients. However, the inter-individual variability in the expression of IFNα, the relative small number of patients, and the cross-sectional design warranted further translational confirmation of these findings in prospective studies.

Studying 33 RA patients during treatment with infliximab, we observed no overall modulation of the expression of type I IFN response genes by TNFα blockade. Further analysis, however, revealed that infliximab induced an upregulation of the type I IFN genes in a subset of patients with a poor clinical response to treatment [52]. In contrast, the type I IFN response genes were not affected in patients with a good response to TNFα blockade. In spondyloarthritis, a disease that responds very well to TNFα blockade, infliximab treatment induced a small decrease of type I IFN serum activity after 2 weeks but the levels returned to baseline after 12 weeks of treatment. TNFα blockade with the soluble TNFα receptor etanercept led to a small increase in type I IFN serum activity after 12 weeks of treatment in a comparable patient population [53]. Similar results
have been reported for patients with SS and inflammatory myopathies. In SS patients, treatment with the soluble TNFα receptor construct etanercept, which is not clinically effective in SS [54], increased serum IFNα activity [9]. In patients with inflammatory myopathies, infliximab induced an increase in type I IFN serum activity without any clinical improvement and even disease exacerbation in some patients [55]. Collectively, these longitudinal studies indicate that the effect of TNFα blockade on type I IFN is not universal and may depend on the disease, the type of TNFα blocker, as well as the clinical response to treatment.

How are TNFα levels and/or activity affected by type I IFN treatment? In healthy volunteers, administration of IFNβ induced a transient decrease of the production of TNFα as well as other inflammatory cytokines such as IL-1β, IL-6 and lymphotokins by PBMCs upon ex vivo stimulation [56]. In MS, IFNβ treatment was also associated with decreased production of TNFα by anti-CD3-stimulated PBMCs. In contrast, concanavalin A-stimulated PBMCs produced more TNFα after IFNβ treatment [57], indicating again that the proposed cross-regulation is not universal but is dependent on factors such as stimulus and cell type. In a proof-of-concept trial in RA patients [27], type I IFN treatment had an immunomodulatory effect on synovial tissue inflammation with decreased levels of synovial TNFα expression in some but not all patients [58]. Conversely, treatment with an anti-IFNα monoclonal antibody downmodulated TNFα mRNA expression in peripheral blood and skin lesions in SLE patients [59]. Before treatment TNFα levels were increased compared with healthy controls, but the levels returned to normal 1 day after anti-IFNα treatment. These data indicate that administration of type I IFNβ may lead to suppression of TNFα production in RA, whereas blocking IFNα does not directly entail elevation of TNFα levels. Consistent with preclinical studies, this experience with targeted interventions in patients highlights the dependence of the interaction between TNFα and type I IFN on the specific type I IFN subtype, the pathogenesis of the disease, and the intrinsic characteristics of the patient.

Clinical relevance of proposed cross-regulation between type I IFN and TNFα

The cellular, experimental, and human data reviewed here indicate that cross-regulation between type I IFN and TNFα may occur in homeostatic conditions but is certainly not a universal principle in IMIDs. The presence or absence of the cross-regulation seems to depend on many factors, including the exact cell type, the type and level of activation, the specific IMID and, within a single IMID, the individual patient. This complexity questions the potential clinical implications of the conceptual framework of type I IFN–TNFα cross-regulation. Three relevant questions in this context are as follows: Can the type I IFN signature in IMID contribute to prediction of response to TNFα blockade? Can successful TNFα blockade induce type I IFN-driven adverse effects? And would IFN treatment be a viable option in TNF-driven IMIDs?

Since not all IMID patients respond well to anti-TNFα therapy, it is very relevant to identify biomarkers predicting clinical efficacy. Could the type I IFN signature be such a biomarker contributing to the prediction of response? The expression of type I IFN response genes are upregulated after TNF blockade, especially in patients who have a poor clinical response to treatment [9,52]. In patients with a good response to treatment, the expression of type I IFN response genes seems unaffected by TNFα blockade.

If the regulation of type I IFN is impeded by successful TNFα blockade, does this subsequently lead to type I IFN-driven adverse events? Type I IFN is known to play an important role in B-cell activation and plasma cell differentiation, and the levels are associated with the presence of autoantibodies in SLE [60]. Accordingly, it is conceivable that modulation of type I IFN by TNF blockade may have an impact on autoantibodies. In RA patients, however, TNF blockade had similar effects on the levels of circulating autoantibodies such as rheumatoid factor or anti-citrullinated protein antibodies in type I IFNhigh patients and type I IFNlow patients [61]. Moreover, the induction of anti-nuclear antibodies by TNF blockade, a phenomenon that is frequently observed in both RA and spondyloarthritis [62], was not related to changes in the serum type I IFN activity [53]. From this we can conclude that there is no influence of the interplay between TNFα and type I IFN with respect to autoantibody production during TNF blockade.

Another intriguing side effect of TNF blockade is the induction of psoriasis-like disease in 3 to 5% of arthritis patients without pre-existing psoriasis, which was completely unexpected considering the excellent clinical response of psoriasis to TNF blockade [63]. This side effect was hypothesized to be due to the proposed cross-regulation between TNFα and type I IFN. Recent studies of human psoriatic tissue demonstrate that IFNα is present early in the disease process but is not detectable in the stable plaque, although downstream IFNα signaling continues to be upregulated. [64]. Indeed, skin biopsies of four patients with anti-TNFα-induced psoriasis displayed increased expression of myxovirus-resistance protein A (a protein specifically induced by type I IFN) compared with biopsies from patients with psoriasis vulgaris [65]. It would be of interest to extend this cohort and analyze in more detail the type I IFN profile to provide formal evidence for the hypothesis that TNFα blockade can induce or enhance type I IFN, and thereby psoriasis, in these patients.
A third clinically relevant question based on the potential cross-regulation is whether type I IFN treatment could be a successful treatment strategy in TNF-driven IMIDs. In animal models for arthritis, a beneficial effect of IFNβ treatment on both swelling and joint destruction has consistently been observed [26,28]. Similar results have been obtained in a collagen-induced arthritis model in rhesus monkeys [27]. A multicenter, randomized, double-blind, placebo-controlled phase II study of subcutaneous IFNβ1a in 209 patients with active RA, however, did not indicate a clinical or radiological effect [66]. This discrepancy might relate to the mode of administration and the difference in IFNβ1a dosages used in man and mice. A successful example of IFNβ treatment is observed in MS, a disease in which TNFα has been shown to play an important role [49]. Further investigation of type I IFN therapy using innovative approaches is thus warranted in RA and other TNF-driven IMIDs.

Conclusion
The present review summarizes the currently available clinical evidence for the proposed cross-regulation between TNFα and type I IFN at the cellular level as well as in vivo in experimental models and in patients with IMIDs (Tables 1 and 2). Since both cytokines have pleiotropic effects that depend on the timing, dosage and cell type, the in vitro studies yielded conflicting results and indicated that the proposed cross-regulation is not as clear cut as anticipated. Moreover, the molecular mechanism of cross-regulation between both cytokines is completely unclear and might be an indirect result through the induction of other factors. Most experimental in vivo models support the concept of cross-regulation between both cytokines but again some studies yielded opposite results, confirming the fact that the cross-regulation may be context dependent.

The studies in patients with different IMIDs show there is not necessarily a direct balance between the levels of type I IFN and TNFα, and that factors such as the type of IMID, the disease phase, and patient heterogeneity may contribute to create a complex picture. It is also possible in patients with IMIDs that both cytokines are elevated and are still influencing each other’s levels from rising even further.

An additional layer of complexity is added by the subtle differences in function of the different subtypes of type I IFN and the difficulty to directly measure these individual isoforms. The usage of type I IFN-induced genes is valuable, but this signature is not always a synonym for the presence of type I IFN specifically. Moreover, how the levels of these cytokines relate to their functional activity and role in disease pathogenesis is still to be investigated.

Abbreviations
ELISA, enzyme-linked immunosorbent assay; IFN, interferon; IL, interleukin; IMID, immune-mediated inflammatory disease; LPS, lipopolysaccharide; MS, multiple sclerosis; NF, nuclear factor; PBMC, peripheral blood mononuclear cell; pDC, plasmacytoid dendritic cell; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SNP, single nucleotide polymorphism; SS, Sjögren’s syndrome; Th, T-helper type; TNF, tumor necrosis factor.

Competing interests
TC, DB and LGMvB have no competing interests. PPT is Chief Scientific Officer of Arthrogen and holds shares in Arthrogen bv. PPT is owner of the following patent: Method for prognosticating the clinical response of a patient to B-lymphocyte inhibiting or depelting therapy.
