PLoS ONE (2011)
**BACKGROUND:** HIV-1-infected macrophages play an important role in rendering resting T cells permissive for infection, in spreading HIV-1 to T cells, and in the pathogenesis of AIDS dementia. During highly active antiretroviral treatment (HAART), macrophages keep producing virus because tissue penetration of antiretrovirals is suboptimal and the efficacy of some is reduced. Thus, to cure HIV-1 infection with antiretrovirals we will also need to efficiently inhibit viral replication in macrophages. The majority of the current drugs block the action of viral enzymes, whereas there is an abundance of yet unidentified host factors that could be targeted. We here present results from a genome-wide association study identifying novel genetic polymorphisms that affect *in vitro* HIV-1 replication in macrophages.

**METHODOLOGY/PRINCIPAL FINDINGS:** Monocyte-derived macrophages from 393 blood donors were infected with HIV-1 and viral replication was determined using Gag p24 antigen levels. Genomic DNA from individuals with macrophages that had relatively low (n=96) or high (n=96) p24 production was used for SNP genotyping with the Illumina 610 Quad beadchip. A total of 494,656 SNPs that passed quality control were tested for association with HIV-1 replication in macrophages, using linear regression. We found a strong association between *in vitro* HIV-1 replication in monocyte-derived macrophages and SNP rs12483205 in *DYRK1A* (p = 2.16 × 10^{-5}). While the association was not genome-wide significant (p < 1 × 10^{-7}), we could replicate this association using monocyte-derived macrophages from an independent group of 31 individuals (p = 0.0034). Combined analysis of the initial and replication cohort increased the strength of the association (p = 4.84 × 10^{-6}). In addition, we found this SNP to be associated with HIV-1 disease progression *in vivo* in two independent cohort studies (p = 0.035 and p = 0.0048).

**CONCLUSIONS/SIGNIFICANCE:** These findings suggest that the kinase DYRK1A is involved in the replication of HIV-1, *in vitro* in macrophages as well as *in vivo*.
INTRODUCTION

The development of highly active antiretroviral therapy (HAART) has been the biggest achievement in HIV/AIDS medicine. The current drug regimens can suppress plasma viral load to (near) undetectable levels. However, often residual levels of ongoing viremia can be detected [1,2], even after treatment intensification [3], and complete eradication of HIV-1 from an infected patient has not been achieved with HAART [4]. HAART does not affect cells that are latently infected because in these cells the virus is not actively replicating. Activation of this viral reservoir of latently infected resting CD4+ T cells [5] and residual replication in monocytes/macrophages (reviewed in [6]) is believed to be responsible for the increase in plasma viral RNA levels that is observed after discontinuing HAART. Furthermore, cells residing in the gut associated lymphoid tissue (GALT) [7,8], the testis [9,10] and the central nervous system (CNS) [11,12] may keep producing virus despite the use of antiretrovirals, because drug penetration in these tissues is suboptimal. As a result of this viral rebound and the existence of these sanctuary sites, HIV-1-infected individuals need to be on anti-HIV-1 medication for life. The emerging drug resistance [13,14] and the severe side effects (reviewed by [15]), high costs and suboptimal tissue penetration of HAART necessitate transition from treatment to cure as soon as possible.

The viral reservoir is established early after primary HIV-1 infection [16,17]. Although the precise mechanism is unknown, it has been shown that infected macrophages play a critical role in rendering resting CD4+ (but CCR5-) T cells permissive for HIV-1 infection [18]. Targeting these HIV-1-infected macrophages will not only help to eradicate the viral reservoir, but will also limit the spread of HIV-1 to CD4+ T cells [19,20], prevent recruitment and activation of these cells [21], and reduce macrophage mediated apoptosis of T cells [22–25]. In addition, inhibiting or reducing HIV-1 replication in macrophages/microglia will be of importance in preventing the onset of AIDS dementia and other neurocognitive disorders associated with HIV-1 infection in the brain, because macrophages/microglia play a crucial role in the pathogenesis of these [26–28].

In the battle to cure HIV-1-infected individuals, identification of novel targets for the development of drugs that can be used to inhibit HIV-1 replication in macrophages will be required, especially since macrophages are relatively resistant to the cytopathic effect of HIV-1 replication [29]. Furthermore, tissue macrophages residing in the sanctuary sites described above are exposed to suboptimal levels of antiretrovirals, and the efficacy of protease inhibitors (PIs) and other late stage inhibitors in macrophages is substantially reduced [30,31]. This lower efficacy of PIs in macrophages forms an obstacle in ending the ongoing residual replication, since only intervention of the virus’ replication cycle at stages post reverse transcription and integration will prevent the production of new virions. Once the provirus is integrated in the host genome, integrase and reverse transcriptase inhibitors will no longer be effective in the cell.
Since the HIV-1 genome encodes only 15 proteins [32], it is dependent on numerous host proteins for its replication [33]. Intervention of the interaction between HIV-1 and these HIV-1 dependency factors (HDFs) can potentially be used to inhibit replication of the virus. Currently, the majority of drugs target viral enzymes: HIV-1 protease, reverse transcriptase and integrase (reviewed in [34]). The abundance of the HDFs offers great promise for finding drugs that may be less prone to emerging drug resistance of the virus, may better penetrate tissues and reach sanctuary sites, and may effectively prevent the formation of new virions in both monocytes/macrophages and CD4+ T cells. However, it will be crucial to find a balance between limiting the availability of HDFs and inhibiting viral replication, since most host proteins essential for HIV-1 replication may also play critical roles in the host cell.

Recently, a large number of host proteins that might be good targets for novel drugs to inhibit HIV-1 replication was identified [35–38]. These candidate proteins were found by measuring a significant change in HIV-1 replication after a genome-scale knock-down of host proteins, in different cell-lines. Since macrophages are important as reservoir and in sanctuary sites, it is also important to identify HDFs or host antiviral factors in these cells. Because primary macrophages are notoriously difficult to transfect and since HIV-1 replication in monocyte-derived macrophages (MDM) can vary enormously between donors [39–43] we decided to use a different approach and to actually exploit this genetic variation between individuals. When monocyte isolation, cell culture methods, medium and virus are all strictly controlled, remaining variation in HIV-1 replication observed in MDM from different donors can be assumed to be primarily of genetic origin. Finding an association between host genetic traits like a single nucleotide polymorphism (SNP) and HIV-1 replication in MDM would suggest that the locus tagged by this SNP is of importance for replication of HIV-1 in these cells. We therefore searched genome-wide for associations between SNPs and in vitro HIV-1 replication specifically in monocyte-derived macrophages.

RESULTS

Association between SNP in the kinase DYRK1A and HIV-1 replication in monocyte-derived macrophages

A total of 494,656 SNPs passing quality control were tested for association with levels of HIV-1 replication in monocyte-derived macrophages (MDM) using linear regression. With data from 191 healthy blood donors whose MDM ranked in the bottom quartile with lowest (n=95 donors) or top quartile with highest (n=96 donors) Gag p24 production 14 days post infection with HIV-1 [39] (Table 3.1), we found strongest associations for SNPs in the genes PDE8A (rs2304418, \( p = 2.4 \times 10^{-6} \) and rs12909130, \( p = 8.3 \times 10^{-6} \)), UBR7 (rs2905, \( p \))
GWAS identifies SNP in DYRK1A associated with HIV-1 replication in MDM

= 7.0 × 10^{-6}, MOAPI (rs1046099, p = 9.9 × 10^{-6} and rs1270629, p = 1.09 × 10^{-5}), DYRK1A (rs12483205, p = 2.2 × 10^{-5}) and SPOCK3 (rs17519417, p = 2.5 × 10^{-5}) (Figure 3.1, Table S3.1). The two SNPs in PDE8A were found to be in high linkage disequilibrium (LD; r^2 = 0.97), whereas only a moderate degree of LD was found between rs1046099 and rs1270629 in MOAPI (r^2 = 0.54) (Table 3.2). Table 3.2 shows all other SNPs associated with HIV-1 replication in MDM (n=16, cutoff p value = 5 × 10^{-5}), and includes information about LD, location, number of donors homozygous for the minor allele (MIN) and empirical p values after permutation testing. Genotyping results for none of these 16 SNPs violated Hardy-Weinberg equilibrium.

The empirical p values for linear regression using 10^7 permutations of the genotype for each SNP in Table 3.2 were in close agreement with the asymptotic p values (Table 3.2). However, none of these SNPs remained statistically significant after a conservative correction for multiple testing (Bonferroni threshold of p < 1 × 10^{-7}; Figure S3.1). We next investigated the association between the SNPs in the five most promising genes (rs2304418 in PDE8A, rs2905 in UBR7, rs1046099 and rs1270629 in MOAPI, rs12483205 in DYRK1A and rs17519417 in SPOCK3) in a second group of blood donors (replication cohort). MDM from an independent group of 32 healthy blood donors were infected with HIV-1 and Gag p24 levels were measured 14 days after infection. One donor was found to be homozygous for the 32 base pair deletion in CCR5, rendering the cells completely resistant to infection with CCR5-using HIV-1, and results obtained with macrophages from this donor were excluded from further analysis. The associations for the SNPs in PDE8A, UBR7, MOAPI and SPOCK3 with Gag p24 production by MDM could not be replicated in this small group of 31 donors (data not shown). However, in this replication cohort we again found
a strong association between SNP rs12483205 in \textit{DYRK1A} and \textit{in vitro} HIV-1 replication in macrophages ($p = 0.0034$) (Figure 3.2, Table S3.2), also after correction for cell number and normalization ($p = 0.0081$; n=28, information on cell number was missing for 3 donors) (data not shown, Table S3.2). This association remained significant after correction for multiple testing (Bonferroni corrected $p = 0.020$ ($0.0034 \times 6$ SNPs for which we tried to replicate the association)) and when calculating the empirical $p$ value for linear regression using $10^5$ permutations of the genotypes ($p = 0.004$) (Table S3.1).

The \textit{DYRK1A} SNP rs12483205 genotypes were then also determined for the 202 donors with MDM that had intermediate Gag p24 levels in the supernatant [39]. Adding results from this group of donors did not change the strength of the association between the rs12483205 genotype and HIV-1 replication in MDM ($p = 2.09 \times 10^{-5}$; n=393) (Figure S3.2A, Table S3.3). As expected, combined analysis of both the initial group of donors (n=393) and the replication cohort (n=28) revealed an increase in the strength of the association for rs12483205 in \textit{DYRK1A} ($p = 4.84 \times 10^{-6}$) (Figure S3.2B, Table S3.4).

![Figure 3.1](image.png)

\textbf{Figure 3.1.} Association between HIV-1 replication in monocyte-derived macrophages (MDM) and the genotypes for the SNPs rs12483205 in \textit{DYRK1A}, rs2304418 in \textit{PDE8A}, rs2905 in \textit{UBR7}, rs1046099 and rs1270629 in \textit{MOAP1}, and rs17519417 in \textit{SPOCK3}. Only donors with MDM with low (n=95) or high (n=96) HIV-1 replication \textit{in vitro} were included in the genome-wide SNP analysis. This selection of donors with a more extreme phenotype explains the absence of circles in the middle section of the graphs. MAJ, homozygous for the major allele; HZ, heterozygote; MIN, homozygous for the minor allele.

Chr., chromosome

¹ The effect of the SNP in *DYRK1A* was replicated with monocyte-derived macrophages from an independent group of 31 donors.

² Empirical *p* value calculated for linear regression using 10⁷ permutations of the genotypes

³ Measure for the magnitude of linkage disequilibrium (*r²*) between SNPs with identical symbols (▲, ◄, ►, ▼, ■, ● or ♦)

⁴ Major genotype is the heterozygous genotype (~50%); both classes of homozygous genotypes equally present (~25% each)
The 32 base pair deletion in \textit{CCR5} strongly affects replication of HIV-1, also in macrophages \textit{in vitro} [39]. MDM from donors that were heterozygous for this 32 base pair deletion (n=33) had significantly lower HIV-1 replication than donors without the deletion (n=158) \((p=0.0036, \text{unpaired } t\text{-test})\) (Table S3.5). There were significantly more \textit{CCR5} \textit{wt}/\textit{Δ32} heterozygous donors present in the \textit{rs12483205} heterozygous (HZ) and \textit{rs12483205} MIN groups \((p=0.02, \text{Fisher Exact test})\). After adjusting for the \textit{CCR5} \textit{wt}/\textit{Δ32} heterozygous genotype by using it as a covariate in multivariate analysis, the strength of the association between the \textit{DYRK1A} \textit{rs12483205} genotype and HIV-1 replication in MDM decreased (from \(p=2.2 \times 10^{-5}\) to \(p=1.2 \times 10^{-4}\)), but persisted (Table S3.5). Moreover, the association of \textit{rs12483205} in \textit{DYRK1A} with HIV-1 replication in MDM in the replication cohort of 31 donors, was independent of the \textit{CCR5} \textit{Δ32} genotype \((p=0.0022, \text{and } p=0.007 \text{when corrected for cell number and normalized for date of isolation}; \text{Table S3.2})\), suggesting only a spurious relationship between the \textit{CCR5} locus on chromosome 3 and SNP \textit{rs12483205} in \textit{DYRK1A} located on chromosome 21. Indeed, this was supported by results from the multivariate analysis on the total group of 393 donors \((p=3.8 \times 10^{-5}, \text{Table S3.3})\) and on the combined group of 421 (393 + 28 donors from the replication cohort) individuals \((p=9.7 \times 10^{-6}, \text{Table S3.4})\).
GWAS identifies SNP in DYRK1A associated with HIV-1 replication in MDM

Minor variant of SNP rs12483205 in DYRK1A is associated with slower disease progression

Next, we investigated the association between HIV-1 load or disease course in vivo and the six most promising SNPs identified in our GWAS (rs12483205 in DYRK1A, rs2304418 in PDE8A, rs2905 in UBR7, rs1046099 and rs1270629 in MOAP1 and rs17519417 in SPOCK3). Results from the Amsterdam Cohort Study (ACS) GWAS on HIV/AIDS disease progression (Van Manen et al., submitted for publication) and three previously published HIV-1 cohort studies with GWAS data were used: the CHAVI cohort [44], the GRIV [45,46] and the MACS [47]. To avoid possible overlap between the replication cohorts, MACS samples were removed from the CHAVI cohort and the analysis was performed only using data from the European subset (EURO-CHAVI).

Illumina Human Hap BeadChips were used for genotyping DNA samples in the EURO-CHAVI cohort (550K/1M), the GRIV (300K) and the ACS (300K), whereas in the MACS they used Affymetrix Human 500K GeneChips for the first stage discovery analysis [47]. Using different genotyping platforms results in genotype data for a different set of SNPs, which occasionally makes it necessary to estimate the unobserved genotypes, a process called SNP imputation [48]. When the imputation score (a measure for the reliability of the imputation) was below 0.8, imputation was considered unreliable and data was therefore not used. Results for SNPs rs2905 (UBR7), rs1046099 (MOAP1), rs1270629 (MOAP1) and rs12483205 (DYRK1A) in the MACS, and rs1046099 (MOAP1) and rs17519417 (SPOCK3) in both the GRIV and the ACS, were based on SNP imputation. The imputation score for rs12483205 in DYRK1A was 0.94, and < 0.8 for rs2905, rs1046099 and rs1270629. For rs1046099 and rs17519417 the imputation scores were 0.88 and 1 respectively, in the GRIV and in the ACS.

Table 3.3 shows the results for association testing between disease progression or viral load and the identified SNPs in DYRK1, PDE8A, UBR7, MOAP1 and SPOCK3. No significant associations or trends were found for the SNPs in PDE8A, UBR7 or MOAP1. However, SNPs rs12483205 in DYRK1A and rs17519417 in SPOCK3 were significantly associated with in vivo endpoints in at least one of the four independent cohorts analyzed. While no association was observed in the GRIV and the ACS, we found an association between rs12483205 in DYRK1A and disease progression in the MACS ($p = 0.0048$, Table 3.3) and in the EURO-CHAVI cohort ($p = 0.035$, Table 3.3). In both cohort studies the minor allele of rs12483205 was associated with slower disease progression, which was consistent with the decreased in vitro replication of HIV-1 in MDM for the minor allele of rs12483205.

Furthermore, there was an association between SNP genotype and progression to AIDS for rs17519417 in SPOCK3 in the MACS [47] ($p = 0.012$, Table 3.3), with the C allele associated with slower progression. This was also in agreement with the association with lower in vitro HIV-1 replication in MDM in our study.

* effect of the minor allele consistent with our findings

# based on SNP imputation; imputation score > 0.8

N.A., not available (imputation score < 0.8); EURO-CHAVI, European subset of the CHAVI cohort (n=1,280 for viral load and n=634 for disease progression) [44]; GRIV, Genomics of Resistance to Immunodeficiency Virus cohort (275 non-progressors vs. 1,352 controls [45], and 85 rapid progressors vs. 1,352 controls [46]); MACS, MultiCenter AIDS Cohort Study cohort (n=156) [47]; ACS, Amsterdam Cohort Study (n=404; Van Manen et al., submitted for publication)

**SNP rs12483205 is localized near the 5' untranslated region of **DYRK1A** transcript variant 3**

The **DYRK1A** mRNA has multiple splice forms. According to the NCBI Entrez Gene database [49] the alternative splicing can yield four different **DYRK1A** transcript variants, referred to as transcripts 1, 2, 3 and 5 (**Figure 3.3**). In addition to differences in the number or size of exons, there is also variation in the length of both the 5' and 3' untranslated region (UTR). Transcript variant 1 encodes the longest isoform (763 amino acids), which is a fraction larger than isoform 2 (754 amino acids). Isoforms 3 and 5 lack a C-terminal part of the full length protein (179 and 234 amino acids respectively), and consequently miss among others a poly-His domain. SNP rs12483205 in **DYRK1A** lies ~900 base pairs downstream of the most distant 5' UTR fragment of transcript variant 3 (**Figure 3.3**). PCR analysis with primers able to discriminate between all four known transcript variants (**Figure S3.3**) confirmed the presence of transcript variants 1, 2 and 3 in MDM, and in the glioma cell line U87 that was used as a positive control for the PCR (**Figure 3.4**). Transcript variant 5 was present in U87 cells, but was not detected in MDM (**Figure 3.4**). The **DYRK1A** gene region is devoid of
GWAS identifies SNP in DYRK1A associated with HIV-1 replication in MDM

known SNPs that are in high LD with rs12483205; currently available data on LD in this region does not reveal any SNP with an $r^2 > 0.5$ in the Caucasian population [50–52].
**DISCUSSION**

Genome-wide studies provide a hypothesis free and unbiased approach to identify novel associations between genetic factors and the studied phenotype. Selecting donors with a more extreme *in vitro* phenotype allowed us to identify a number of promising SNPs in genes not previously linked to HIV-1, that are associated with replication levels of HIV-1 in monocyte-derived macrophages (MDM). Importantly, the association between rs12483205 in *DYRK1A* and *in vitro* HIV-1 replication could be replicated using MDM from an independent small group of donors, and was independent of the *CCR5* Δ32 genotype. Moreover, this SNP in *DYRK1A* was significantly associated with *in vivo* endpoints in two independent cohorts. SNPs in four other genes were not replicated in the small *in vitro* replication cohort, possibly reflecting insufficient power. However, the identified SNP in *SPOCK3* was replicated in one of the *in vivo* GWAS.

The use of, or even the dependence on, certain cellular factors by HIV-1 can differ between the various target cells such as T cells and macrophages. For example, the cellular factors GATA-3, ETS-1 and NF-ATc are T cell specific [53,54], whereas C/EBPβ is required for HIV-1 replication in macrophages, but not in T cells [55,56]. To test whether our top SNPs were macrophage-specific, we investigated if these SNPs were also associated with HIV-1 replication in CD4+ T cells. Genotyping DNA from 128 blood donors for whom the level of HIV-1 replication in PHA-stimulated CD4+ T cells was previously determined [57], revealed no association between the level of HIV-1 replication in T cells and the genotype of the five SNPs tested. This finding could indeed be an indication that the effects of some of the SNPs that we have identified are macrophage-specific, but also could reflect lack of power (n=128, and not only extreme phenotypes). The finding that the SNP rs12483205 in *DYRK1A* was associated with *in vivo* endpoints could indicate a role for HIV-1 infection of macrophages in disease progression.

*DYRK1A* is a kinase that phosphorylates serine and threonine residues. The gene coding for this kinase is located on the Down syndrome critical region on chromosome 21 which is thought to be responsible for the features of Down syndrome. For this reason, the emphasis of *DYRK1A* research has been on its role in trisomy 21 and neurological dysfunction [58–63]. Substrates for *DYRK1A* comprise among many others the transcription factors CREB [64], FKHR [65], GLI1 [66], NFAT [67,68] and STAT3 [69]. This large number of protein interactions and substrates described for *DYRK1A* strongly suggests it plays an important role in the regulation of gene expression and cell function. While the molecular mechanisms underlying the effect of *DYRK1A* on HIV-1 replication in MDM remain to be unraveled, the critical role of kinases in general for the replication of HIV-1 in macrophages has already been established [70–75].

Both SNPs in *MOAP1* that we found to be associated with HIV-1 replication in MDM are in close proximity to the UBR7 gene region (44 and 47 kb for rs1046099 and rs1270629...
GWAS identifies SNP in DYRK1A associated with HIV-1 replication in MDM

respectively), yet the degree of LD is fairly low ($r^2 = 0.28$ and 0.35 for rs1046099 and rs1270629 respectively) which could indicate that the observed associations for the SNPs in UBR7 and MOAP1 with HIV-1 replication are independent of each other. MOAP1 is a homodimeric protein that binds both proapoptotic (BAX) and pro-survival (BCL2) molecules [76]. MOAP1 has no known direct effect on HIV-1 replication. However, it is well recognized that HIV-1 infection affects the regulation of programmed cell death (reviewed in [77]) and that host factors induce apoptosis during the infection process to prevent viral dissemination [78,79]. This host factor-induced apoptosis was found to be associated with reduced HIV-1 replication in MDM [78,79]. Only very little is known about UBR7. However, studies on other members of the UBR family support the hypothesis that UBR7 is associated with HIV-1 replication. Proteins of the UBR family are E3 ligases that recognize degradation signals at the N-terminus of proteins (N-degrons) and conjugate ubiquitin to the target protein [80]. The HIV-1 protein integrase contains an N-terminal phenylalanine that is recognized as a degradation signal by UBR1, UBR2 and UBR4 [80,81] and indeed, these proteins control the level of HIV-1 integrase [80]. Knocking down UBR1, UBR2 and UBR4 resulted in higher levels of HIV-1 integrase [80], yet inhibition of the proteasome resulted in a further increase of HIV-1 integrase [80], suggesting the presence of other E3 ligases that target N-degrons of HIV-1 integrase. The results of our study could indicate that UBR7 affects HIV-1 replication in MDM through regulation of HIV-1 integrase.

In addition to the SNP in DYRK1A we also found associations for rs17519417 in SPOCK3 with time to progression to AIDS. SPOCK3, also referred to as Testican 3, is a proteoglycan and one of the components of the extracellular matrix. It inhibits processing of metalloproteinase 2 (MMP-2) [82]. There are indications that MMP-2 might play a role in the pathogenesis of AIDS-related Kaposi’s sarcoma [83,84] or HIV-1-associated dementia [85–87].

While we could not replicate the GWAS result for the SNP in PDE8A, results from other in vitro studies strongly suggest that PDE8A plays an important role in the replication cycle of HIV-1. Phosphodiesterase 8A (PDE8A) specifically hydrolyses cAMP to AMP. Previous studies that showed strong inhibition of HIV-1 replication after efficient knock-down [38], interaction between HIV-1 Tat protein and PDE8A [88,89] and the deleterious effect of high levels of cAMP on HIV-1 replication [90], all profoundly suggest that this type of phosphodiesterase is indeed important for in vitro HIV-1 replication.

To further validate our findings it will be important to also investigate the role of the identified SNPs and genes in HIV-1-related pathologies that are more specifically affected by macrophages, such as HIV-1-associated dementia and AIDS-related lymphomas [91]. Here, the contribution of macrophages could be more eminent than in cohorts that study time to progression to AIDS, which might be more T cell dependent, especially since sometimes AIDS is defined by CD4+ T cell counts.
Follow-up experiments that will identify the causal SNP and study its effect on the primary protein structure, protein folding, alternative splicing or expression (level, localization and timing) will be essential to better understand the precise mechanism by which this SNP affects HIV-1 replication in MDM. This will be a valuable step that might help determine if, and to what extent the host protein can be efficiently targeted by novel antiretroviral drugs. Finding a SNP in a gene encoding the kinase DYRK1A that affects HIV-1 replication, holds great promise for finding molecules to be safely used as potentially novel anti-HIV-1 medication [92].

MATERIALS AND METHODS

Ethics statement

This study has been conducted in accordance with the ethical principles set out in the declaration of Helsinki, written informed consent was obtained from all participants and was approved by the Medical Ethics Committee of the Academic Medical Center in Amsterdam and the Ethics Advisory Body of the Sanquin Blood Supply Foundation, The Netherlands.

Study population

We previously determined the ability of HIV-1 to replicate in monocyte-derived macrophages (MDM) from 429 different healthy seronegative blood donors [39]. In brief, Gag p24 levels were measured in MDM culture supernatant 14 days post infection by an in-house enzyme-linked immunosorbent assay. To correct for differences in the number of viable MDM present at day 14 post infection, p24 levels were expressed per 10,000 cells. Since monocyte isolations were performed in four time frames and by two operators, p24 levels were normalized by dividing through the median per period and operator. These normalized p24 levels were subsequently used as a measure for in vitro HIV-1 replication in MDM.

After excluding donors that were homozygous for the 32 base pair deletion in CCR5 (n=5) or not from European decent (n=30), we selected 192 individuals whose MDM gave the highest (n=96) or the lowest (n=96) p24 production in vitro, for SNP genotyping; thus representing two groups of donors with MDM that had a more extreme phenotype (Table 3.1). Inclusion of donors with extreme phenotypes is known to increase power in genetic association studies [93]. These two groups with a more extreme phenotype were separated by a group with intermediate HIV-1 replication in MDM which consisted of 202 donors. There was no difference in age or distribution of males and females between the group with MDM that had low HIV-1 replication and the group with MDM that had high Gag p24 production (p = 0.95, Pearson chi-square test and p = 0.37, unpaired t-test, respectively; Table 3.1).
GWAS identifies SNP in DYRK1A associated with HIV-1 replication in MDM

One donor from the group with low \textit{in vitro} HIV replication in MDM was excluded for further analysis because the corresponding DNA samples did not pass the quality control (SNP call rate < 0.98; see paragraph “Quality control of SNP genotyping data” below).

Cells (monocytes and lymphocytes) used to replicate the genome-wide association study (GWAS) findings were derived from blood samples collected from an independent group of 32 healthy blood donors (replication cohort).

\textbf{Genotyping}

Peripheral blood lymphocytes (PBL) from each donor were used for DNA isolation using the QIAamp “DNA blood mini kit” (Qiagen, Valencia, CA, USA). For the two groups of donors whose MDM had highest (n=96 donors) or lowest (n=96 donors) \textit{in vitro} HIV Gag p24 production, we used the Illumina Infinium Human Hap 610-Quad BeadChip (Illumina, San Diego, CA, USA) [94] for SNP genotyping. ABI TaqMan® SNP genotyping assays were used to genotype DNA from the replication cohort for rs12483205 (C\_31609775\_10), rs12909130 (C\_1342209\_10) as a proxy for rs2304418, rs2905 (C\_3236245\_20), rs1046099 (C\_7585751\_10) and rs17519417 (C\_33238869\_10) (Applied Biosystems, Carlsbad, CA, USA). All TaqMan® assays were run on a LightCycler® 480 system (Roche, Basel, Switzerland) using the following amplification cycles: 10 min 95 °C; 50 cycles of 15 sec 95 °C, 1 min 60 °C.

\textbf{Quality control of SNP genotyping data}

One donor DNA sample did not pass the minimal genotyping call rate threshold of 98% and this sample was excluded for further SNP association analysis. The Illumina 610Q SNP beadchips contained 620,901 markers to detect common genetic variation, including 21,890 markers for copy number variation (CNV). After excluding a total of 126,245 SNPs (minor allele frequency < 0.05, or SNP call frequency < 0.98, or SNPs for which there were no donors homozygous for the minor allele) and copy number variation markers, 494,656 SNPs were left to be tested for association between genotype and \textit{in vitro} HIV-1 replication MDM. Violation of Hardy-Weinberg equilibrium was assessed post-analysis for all SNPs with \( p < 5 \times 10^{-5} \). Gender calls in BeadStudio (version 3.1.3.0) were compared with self-reported gender and were found to match for all donors (n=191).

\textbf{Identification of population stratification}

Donors who reported that either one or more parents or grandparents were born outside of Europe had been excluded from further analysis (as described in the paragraph “Study population” above). The genetic homogeneity of the genotyped donors whose MDM gave lowest
(n=96) or highest (n=96) Gag p24 production in vitro was confirmed by both Structure [95] and Eigenstrat [96] analysis. As expected, the Q-Q plot displaying the normality of the p value distribution did not show deviations from what is expected under the null hypothesis ($\lambda = 1.0024; \lambda = 1.0$ is expected with a null hypothesis; Figure S3.4), indicating little effect of population stratification.

**Statistical analysis**

We set a lower detection limit (background signal) for the normalized p24 values based on the highest result that we found for donors homozygous for the 32 base pair deletion in CCR5. Normalized p24 values were log10 transformed to allow for parametric testing.

Association was tested assuming an additive relationship between the genetic variants (wild-type, heterozygous and homozygous for the minor allele) and phenotype, using linear regression. Permutation testing was done to empirically determine the corresponding p value based on the observed linear regression F-statistic relative to the distribution of the F-statistic estimated from $10^7$ permutations of the genotypes. All R code and data used for the calculations can be found as supplementary online material (Tables S3.1–3.5 and text file “R scripts S3.1”).

Linkage disequilibrium (LD) between SNPs was calculated using data obtained from genotyping DNA from our studied population (n=191) with the Illumina SNP chip, using Haploview software (version 4.2) [50]. SNP genotype imputations for our study population were performed using Impute software [48] and the Caucasian HapMap population (release 21) as the reference panel.

**DYRK1A transcript detection in monocyte-derived macrophages**

Seven day old MDM and U87 cells were used for RNA isolation and subsequent cDNA synthesis using the Roche “high pure RNA isolation” and “transcriptor first strand cDNA synthesis” kit (Roche, Basel, Switzerland). To uniquely detect the presence of transcript variants 1, 2, 3 and 5, we used primer pairs 5’-TGATATTGTCATGTTACAGAGGCGG-3’ (forward) and 5’-CTGACGCACCTGAGGTGACTG-3’ (reverse), 5’-TGTCTCTGAGGT-TCTTTTCCAGTG-3’ (forward) and 5’-AGCACCCCTCTCAATTCCCAATGCC-3’ (reverse), 5’-GCTTCAGTCGTTATTTGCTGCT-3’ (forward) and 5’-TCCTTAGACGGAACGTATCACTGAACCT-3’ (reverse), and 5’-CAGGAGGACCTGGTGGGCGA-3’ (forward) and 5’-TGTCTGACGCACCTGAGGTGCT-3’ (reverse) respectively (Figure S3.3).

For the detection of transcript variants 1, 2, 3 and 5 the following amplification cycles were used: 2 min 95°C; 35 cycles of 30 sec 95°C, 30 sec 62°C (64°C for transcript 1), 30 sec 72°C (90 sec for transcript 1); 10 min 72°C.
GWAS identifies SNP in *DYRK1A* associated with HIV-1 replication in MDM

Tables S3.1–S3.5 and text file “R scripts S3.1” are not printed in this thesis, but are available upon request.

**ACKNOWLEDGEMENTS**

The authors acknowledge funding from the Landsteiner Foundation Blood Research (registration number 0526) and the European Union (Marie Curie International Reintegration Grant 029167). We are indebted to all blood donors for their participation in this study, and thank Susan Cuvalay, Rachid Essinouh, Reno Frissen, Colinda Kroes, Cheryl Land, and all other employees at Sanquin Blood Bank for logistics. We would like to thank Evelien Bunnik for critical reading of the manuscript, Amalio Telenti and Marga Rotger for kindly sharing DNA from the donors used for their *in vitro* HIV-1 replication study in CD4+ T cells, Sigrid Le Clerc for sharing her part of the GRIV GWAS data, and Olivier Delaneau for his helpful advice on SNP imputation. Finally, we acknowledge Thomas Lumley for help with the design of the statistical analysis.

MACS data in this manuscript were collected by the Multicenter AIDS Cohort Study (MACS) with centers (Principal Investigators) at The Johns Hopkins Bloomberg School of Public Health (Joseph B. Margolick, Lisa P. Jacobson), Howard Brown Health Center, Feinberg School of Medicine, Northwestern University, and Cook County Bureau of Health Services (John P. Phair, Steven M. Wolinsky), University of California, Los Angeles (Roger Detels), and University of Pittsburgh (Charles R. Rinaldo). The MACS is funded by the National Institute of Allergy and Infectious Diseases, with additional supplemental funding from the National Cancer Institute. UO1-AI-35042, UL1-RR025005 (GCRC), UO1-AI-35043, UO1-AI-35039, UO1-AI-35040, UO1-AI-35041.
**SUPPLEMENTAL FIGURES**

**Figure S3.1.** Manhattan plot displaying the -log \( p \) value of the association for 494,656 SNPs tested with *in vitro* replication of HIV-1 in monocyte-derived macrophages. Signals are seen for SNPs in chromosome 14 (SNPs in *UBR7* or *MOAP1*), 15 (SNPs in *PDE8A*) and 21 (SNP rs12483205 in *DYRK1A*, and intergenic SNP rs2828074 > 14 Mb upstream of rs12483205). The threshold for genome-wide significance is -log \( p > 7 \) (dashed line). The plot was created using the WGA viewer software version 1.26G [97].

**Figure S3.2.** Association between HIV-1 replication in monocyte-derived macrophages (MDM) and the SNP rs12483205 genotype in the gene *DYRK1A*, for the total group of 393 blood donors (A), and this group of donors joined with donors from the replication cohort for which we had normalized data (n=28; total n=421) (B). DNA from donors with MDM that had low (n=95) or high (n=96) HIV-1 replication *in vitro* was used for the genome-wide association screen. Inclusion of genotype and normalized p24 data from donors with MDM that had intermediate Gag p24 production did not change the strength of the association (\( p = 2.09 \times 10^{-5} \)), whereas combining the initial group of donors (n=393) and the replication cohort (n=28) increased the strength of the association (\( p = 4.84 \times 10^{-6} \)). MAJ, homozygous for the major allele; HZ, heterozygote; MIN, homozygous for the minor allele.
GWAS identifies SNP in *DYRK1A* associated with HIV-1 replication in MDM

**DYRK1A mRNA alignment**

Figure S3.3. Schematic representation of the alignment of all four known *DYRK1A* mRNAs. Primers are depicted as arrows and were used to amplify a unique region for each of the transcripts. The start and stop codons are shown as vertical lines.

![DYRK1A mRNA alignment](image)

Figure S3.4. Q-Q plot showing the expected and observed distribution of the $p$ values. The line and the corresponding Lambda ($\lambda$) suggest there are no systematic differences in allele frequencies between subpopulations in our study population due to differences in genetic background of donors. The plot was created using the WGA viewer software version 1.26G [97].
