Search for the Standard Model Higgs boson in the two photon decay channel with the ATLAS detector at the LHC

The ATLAS Collaboration

1. Introduction

The search for the Standard Model Higgs boson [1–3] is one of the key goals of the Large Hadron Collider (LHC) at CERN. The allowed Higgs boson mass ($m_H$) is constrained at the 95% confidence level by a lower limit of 114.4 GeV from the LEP experiments [4] and an excluded region between 156 and 177 GeV from the Tevatron experiments [5,6]. First results have been reported by the ATLAS experiment in a variety of channels [7] and the CMS experiment [8] using the data recorded in 2010, which correspond to an integrated luminosity about thirty times smaller than the 2011 dataset used in this analysis.

In the low mass range, from the LEP limit to $m_H \approx 140$ GeV, one of the most promising search channels at the LHC is the rare decay of the Higgs boson into a pair of photons. Despite the low branching ratio ($\approx 0.2\%$), this channel provides good experimental sensitivity in the mass region below 150 GeV. The results presented in this Letter are based on proton–proton collision data taken at $\sqrt{s} = 7$ TeV by the ATLAS experiment between April and June 2011.

The data analysis proceeds by selecting photon pairs with tight identification and isolation cuts to minimize backgrounds other than direct diphoton production. A narrow peak in the reconstructed invariant mass distribution is searched for over a large, smooth background whose normalisation and shape are left free in a maximum likelihood fit. To increase the sensitivity, the sample is divided into five categories based on the presence of photon conversions and on the photon impact point on the calorimeter, with different invariant mass resolutions and signal-to-background ratios for the different categories.

The results of the fit are compared to the prediction from the Standard Model using the Higgs boson production cross-section and branching ratio from Ref. [9]. Limits on the production cross-section relative to the Standard Model value are then derived as a function of the hypothesised Higgs boson mass. Although with the current dataset the analysis is not yet sensitive to the predicted rate for a Standard Model Higgs boson, the limits on the yield in this decay channel improve on those obtained in the same channel by the Tevatron experiments [10–12], and are sensitive to possible enhancements in the Higgs boson production and decay rate compared with the Standard Model expectations.

2. Experimental setup and data set

The ATLAS detector is described in detail in Ref. [13]. The main subdetectors relevant to this analysis are the calorimeter, in particular its electromagnetic section, and the inner tracking detector.

The electromagnetic calorimeter is a lead–liquid argon sampling calorimeter with accordion geometry. It is divided into a barrel section covering the pseudorapidity region $|\eta| < 1.4$ and two end-cap sections covering the pseudorapidity region $1.375 < |\eta| < 3.2$. It has three longitudinal layers. The first one, with a thickness between 3 and 5 radiation lengths, has a high granularity in $\eta$ (between 0.003 and 0.006 depending on $\eta$, with the exception of the regions $1.4 < |\eta| < 1.5$ and $|\eta| > 2.4$), sufficient to provide discrimination between single photon showers and two photons from a $\pi^0$ decay. The second layer has a thickness of around 17 radiation lengths and a granularity of $0.025 \times 0.025$ in $\eta \times \phi$.

---

ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the $z$-axis along the beam pipe. The $x$-axis points from the IP to the centre of the LHC ring, and the $y$-axis points upward. Cylindrical coordinates ($r, \phi$) are used in the transverse plane, $\phi$ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta = -\ln \tan(\theta/2)$.

* E-mail address: atlas.publications@cern.ch.
A third layer, with a thickness varying between 4 and 15 radiation lengths, is used to correct for leakage beyond the calorimeter for high energy showers. In front of the calorimeter, a thin presampler layer, covering $|\eta| < 1.8$, is used to correct for fluctuations in upstream energy losses. The sampling term $\sigma$ of the energy resolution, $\sigma(E)/E \approx a_1/\sqrt{E}$ (GeV), varies between 9% and 14% as a function of $|\eta|$ for unconverted photons [14]. It reaches up to 20% for converted photons near $|\eta|$ of 1.3 where the upstream material effect is the largest. The sampling term is the largest contribution to the resolution up to about 100 GeV, where the constant term starts to dominate. After 0.17 fb$^{-1}$ of data were accumulated, some calorimeter cells could not be read out. The affected region size is $\Delta \eta \times \Delta \phi \approx 1.5 \times 0.2$ in the barrel electromagnetic calorimeter, resulting in an acceptance loss for diphoton candidates of about 3%. A hadronic sampling calorimeter is located behind the electromagnetic calorimeter. It is made of steel and scintillating tiles in the barrel section, and of copper and liquid argon in the end-caps.

The inner detector consists of three subsystems: at small radial distance $R$ from the beam axis ($5 < R < 15$ cm), pixel silicon detectors are arranged in three cylindrical layers in the barrel and in three disks in each end-cap; at intermediate radii ($30 < R < 56$ cm), double layers of single-sided silicon microstrip detectors are used, organised in four cylindrical layers in the barrel and nine disks in each end-cap; at larger radii ($56 < R < 107$ cm), a straw tracker with transition radiation capabilities is used. These three systems are immersed in a 2 T axial magnetic field. The silicon pixel and strip subsystems cover the range $|\eta| < 2.5$, while the transition radiation tracker acceptance is limited to the range $|\eta| < 2.0$. The inner detector allows reconstruction of secondary vertices, in particular of photon conversions occurring in the inner detector material up to a radius of $\approx 80$ cm.

The total amount of material in front of the first active layer of the electromagnetic calorimeter (including that in the presampler) varies between 2.5 and 6 radiation lengths as a function of pseudorapidity, excluding the transition region ($1.37 < |\eta| < 1.52$) between the barrel and the end-caps.

Data used in this analysis were selected using a di-photon trigger with a 20 GeV transverse energy threshold on each photon. At the first trigger level, which uses reduced granularity, two clusters with transverse energies above 14 GeV are required in the electromagnetic calorimeter. At the higher trigger levels, loose photon identification cuts are applied using the full calorimeter granular-resolution. Closure of the photon reconstruction efficiency is $\approx 99\%$ for the signal after the final event selection. In these data, the instantaneous luminosity varies between $\approx 10^{32}$ cm$^{-2}$s$^{-1}$ and $\approx 10^{33}$ cm$^{-2}$s$^{-1}$ with a bunch spacing of 50 ns. The average number of collisions per bunch crossing is around 6. Collisions in the same bunch crossing as the signal or in other bunch crossings within the detector sensitive time (out-of-time pileup) influence the event reconstruction. The inner detector is only sensitive to in-time pileup while the electromagnetic calorimeter is sensitive to pileup within a $\approx 450$ ns time window.

The application of beam, detector, and data-quality requirements to the recorded data results in a data sample corresponding to a total integrated luminosity of $(1.08 \pm 0.04)$ fb$^{-1}$ [15].

### 3. Simulated samples

The Higgs boson signal from the dominant gluon fusion production process (corresponding to 86% of the production cross-section for a Higgs boson with a mass of 120 GeV) is generated with POWHEG [16]. MC@NLO [17] is used as a cross-check. POWHEG [18] is also used to generate the signal events from the sub-leading vector boson fusion process (7% of the cross-section at 120 GeV). For the other production modes, namely associated production with a $W$ or $Z$ boson or a $t \bar{t}$ pair, PYTHIA [19] is used.

The predicted signal is normalised using NNLO cross-sections for the gluon fusion process [20–24], the vector boson fusion process [25], the associated production with a $W$ or $Z$ boson [26] and NLO cross-section for the associated production with a $t \bar{t}$ pair [27]. The NLO electroweak corrections are applied to the gluon fusion [28,29], vector boson fusion [30,31], and the associated production with a $W$ or $Z$ boson [32] processes. The uncertainty on the theoretical cross-section is estimated [9] to be $\pm 20\%$, mostly due to the renormalisation and factorisation scale variations and the uncertainties in the parton distribution functions [33–36]. The Higgs boson decay branching fractions are taken from Refs. [9,37]. The uncertainty on the branching ratio to two photons is negligible compared with the cross-section uncertainty.

Signal events are generated in steps of 5 GeV for Higgs boson masses in the range of 110–150 GeV. PYTHIA and ALPGEN [38] have been chosen to generate the background samples, which are, however, only used for cross-checks and not to extract the final results.

All Monte Carlo (MC) samples are processed through a complete simulation of the ATLAS detector [39] using the GEANT4 programme [40]. Pileup effects are simulated by overlaying each MC event with a variable number of MC inelastic $pp$ collisions, taking into account both in-time and out-of-time pileup and the LHC bunch train structure. MC events are weighted to have the same distribution of average number of interactions per bunch crossing as in the data.

### 4. Photon reconstruction, event selection and backgrounds

#### 4.1. Photon reconstruction

Photon reconstruction is seeded by energy clusters in the electromagnetic calorimeter with transverse energies exceeding 2.5 GeV in projective towers of size $0.075 \times 0.125$ in $\eta \times \phi$ made from the presampler and the three electromagnetic calorimeter layers. These energy clusters are then matched to tracks that are reconstructed in the inner detector and extrapolated to the calorimeter. Clusters without matching tracks are classified as unconverted photon candidates. Clusters matched to either pairs of tracks which are consistent with the hypothesis of a photon conversion or single tracks without hits in the pixel layer nearest to the beam pipe are considered as converted photon candidates. The photon reconstruction efficiency is $\approx 98\%$.

The energy measurement is made in the electromagnetic calorimeter using a cluster size which depends on the photon classification. In the barrel, a size of $0.075 \times 0.125$ in $\eta \times \phi$ is used for unconverted photons and $0.075 \times 0.175$ for converted photon candidates, to account for the larger spread of the shower in $\phi$ for converted photons due to the magnetic field. In the end-cap, a cluster size of $0.125 \times 0.125$ is used for all candidates. A dedicated energy calibration [14] is applied to account for upstream energy losses, lateral leakage and longitudinal leakage, separately for converted and unconverted photon candidates.

The final energy calibration is determined from $Z \rightarrow ee$ decays, resulting in $\eta$-dependent correction factors of the order of $\pm 1\%$. After this calibration procedure, the constant term in the energy resolution is estimated to be $1.1^{+0.5}_{-0.6}$ in the barrel region and $1.8^{+0.5}_{-0.6}$ in the end-cap region [41]. The energy resolution in the simulation is adjusted to match these values.

Photon identification is based on the lateral and longitudinal energy profiles of the shower in the calorimeter [42]. The photon candidate is required to deposit only a small fraction of its en-
ergy in the hadronic calorimeter. The transverse shower shape in
the second layer of the electromagnetic calorimeter needs to be
consistent with that expected for a single electromagnetic shower.
Finally, the high granularity first layer is used to discriminate sin-
gle photons from overlapping photon pairs from neutral meson
decays produced in jet fragmentation, which are the main back-
ground source. Based on these criteria, a set of tight identification
cuts, different for converted and unconverted candidates, is ap-
plicated.

To take into account small differences in shower shapes be-
tween data and simulation, the shape variables are shifted in the
simulation before the identification cuts are applied. The photon
identification efficiency ranges typically from 75% to 90% for trans-
verse energies between 25 and 100 GeV.

To increase the background rejection, an isolation cut is applied.
The isolation variable \[42\] is computed by summing the trans-
verse energy in calorimeter cells in a cone of radius 0.4 in the \[\eta \times \phi\] space around the photon candidate. Cells in the electromag-
netic calorimeter within \((0.125 \times 0.175)\) from the shower barycentre
are excluded from the sum. The small photon energy leakage out-
side the excluded cells is evaluated as a function of the transverse
energy in simulated samples and is subtracted from the iso-
lolation variable. To reduce the effect from the underlying event and
pileup, the isolation is further corrected using a method suggested in
Ref. [43]: for each of the two different pseudorapidity regions
\(|\eta| < 1.5\) and \(1.5 < |\eta| < 3.0\), low energy jets are used to compute an “ambient” energy density, which is then multiplied by the area
of the isolation cone and subtracted from the isolation energy.

In the following, photon candidates having isolation transverse
energies lower than 5 GeV are considered as isolated. The iso-
lolation cut efficiency is checked in data using a control sample of
\(Z \rightarrow ee\) events. The per-event efficiency of requiring both electrons
to be isolated is found to be 3% lower in the data than in the sim-
lulated samples. In the MC, the isolation cut efficiency is found to
be the same for \(Z \rightarrow ee\) and \(H \rightarrow \gamma\gamma\) events \((\approx 93\%)\). The num-
ber of events predicted by the simulation after the isolation cut is
therefore reduced by 3%.

4.2. Event selection

Two photon candidates are required to pass tight identification
criteria, to be isolated, and to be within the region \(|\eta| < 2.37\), ex-
cluding \(1.37 < |\eta| < 1.52\), where the first calorimeter layer has
high granularity. The highest and second highest photon transverse
energies are required be above 40 and 25 GeV respectively. Both
photons must be clear of problematic regions in the calorimeter.
As the goal is to investigate Higgs boson mass hypotheses between
110 and 150 GeV, the invariant mass of the photon pair is required
to be within 100–160 GeV. After these cuts 5063 events remain in
the selected data sample.

The acceptance of the kinematic cuts, as estimated with gener-
atated photons in the MC signal samples, is 60% for the dominant
gluon fusion process for a mass of 120 GeV. The overall event
selection efficiency, taking into account both kinematic cut ac-
tecessity and reconstruction and identification efficiencies, is 39%. The
event selection efficiency is slightly larger in the vector boson fu-
sion process. It is somewhat smaller in the associated production
mode. It increases with the Higgs boson mass from 34% at 110 GeV
to 43% at 150 GeV.

To enhance the sensitivity of the analysis, the data sample is
split in five categories, with different invariant mass resolutions
and different signal-to-background ratios:

- Unconverted central (8% of the candidates): Both photons are
  unconverted and in the central part of the barrel calorimeter

</tbody>
</table>

\(|\eta| < 0.75\). This is the category with the best invariant mass resolution and the best signal-to-background ratio:

- Unconverted rest (28% of the candidates): Both photons are
  unconverted and at least one photon does not lie in the central
  part of the barrel calorimeter;
- Converted central (7% of the candidates): At least one photon
  is converted and both photons are in the central part of the
  barrel calorimeter;
- Converted transition (16% of the candidates): At least one pho-
  ton is converted and at least one photon is near the transi-
  tion between barrel and end-cap calorimeter \((1.3 < |\eta| < 1.75)\).

Table 1 shows the cross-section times branching ratio and expected number of signal events after all
cuts (total and per category), for various Higgs boson masses and for an integrated luminosity of 1.08 fb\(^{-1}\).

4.3. Invariant mass reconstruction

In addition to the energies, the angle between the photons is
needed for the computation of the diphoton invariant mass. This
angle is determined from the interaction vertex position and the
photon impact points in the calorimeter. The resolution of the
angle measurement is dominated by the reconstruction of the pri-
mary vertex \(z\) position. The RMS vertex spread in the \(z\) direction
is \(\approx 5.5\) cm, and a more accurate event-by-event estimate is per-
fomed to reduce the impact on the invariant mass resolution.
Given the non-negligible level of pileup in the 2011 data, the de-
termination of the vertex position is based only on the photon
candidates, without relying on other charged tracks in the event.
For converted photons with tracks having a precise measurement
in the \(z\) direction, the vertex position is estimated from the in-
tercept of the line joining the reconstructed conversion position
and the calorimeter impact point with the beam line. For all other
photons, the vertex position is estimated from the shower position
measurements in the first and second layers of the electromagnetic
calorimeter, which can be used to calculate the photon direction.
Finally, the vertex positions from both photons are combined tak-
ing also into account the average beam spot position in \(z\). When
both photons are unconverted, the typical vertex position reso-

n ution is \(\approx 1.6\) cm in \(z\). The resolution is better in events with
converted photons. The resulting impact of the angle measurement
on the invariant mass resolution is negligible compared to the con-
tribution from the photon energy resolution.
Fig. 1. Distribution of the reconstructed diphoton invariant mass of a simulated 120 GeV mass Higgs boson signal, for all categories together. The line shows the fit of the mass resolution using the function described in the text. The core component of the mass resolution is 1.7 GeV.

Fig. 1 shows the invariant mass distribution for simulated Higgs boson events with mass 120 GeV. The mass resolution for the signal is modelled by the sum of a Crystal Ball function [44] (for the bulk of the events which have a narrow Gaussian spectrum in the peak region and tails toward lower reconstructed mass) and a Gaussian distribution with a wide sigma (to model the far outliers in the distribution). The Crystal Ball function is defined as:

\[
N \cdot \begin{cases} 
    e^{-t^2/2} & \text{if } t > -\alpha_{CB}, \\
    \left(\frac{n_{CB}}{\sigma_{CB}}\right)^{n_{CB}} \cdot e^{-\frac{t^2}{2\sigma_{CB}^2}} \cdot \left(\frac{n_{CB}}{\sigma_{CB}} - \alpha_{CB} - t\right)^{-n_{CB}} & \text{otherwise}
\end{cases}
\]

where \( t = (m_{\gamma\gamma} - \mu_{CB})/\sigma_{CB} \), \( N \) is a normalisation parameter, \( \mu_{CB} \) is the peak of the narrow Gaussian distribution, \( \sigma_{CB} \) represents the Gaussian resolution for the core component, and \( n_{CB} \) and \( \alpha_{CB} \) parametrise the non-Gaussian tail.

The core component of the mass resolution, \( \sigma_{CB} \), ranges from 1.4 GeV in the “Unconverted central” category to 2.1 GeV in the “Converted transition” category. The non-Gaussian contributions to the mass resolution arise mostly from converted photons with at least one electron losing a significant fraction of its energy through bremsstrahlung in the inner detector material.

4.4. Sample composition

The main background components are the diphoton production, the photon-jet production with one fake photon from jets fragmenting into a high energy \( \pi^0 \), the dijet production with two fake photons, and Drell–Yan events where both electrons are misidentified as photons. A measurement of the diphoton production cross-section with 2010 ATLAS data can be found in Ref. [45], where the techniques used to estimate the purity of the sample are described in more detail. Although the final result does not rely on it, a quantitative understanding of the sample composition is an important cross-check of the diphoton selection procedure.

A method based on the use of control regions for two discriminating variables is applied to measure the contributions of fake photon background directly from the data. This method exploits relaxed isolation and photon identification cuts to estimate the fake components, by relying on the fact that the rejections from these two cuts are almost independent. It is a generalisation of the method used in Ref. [42]. The Drell–Yan background is estimated by measuring the probability for an electron to be reconstructed as a photon candidate with \( Z \) events and applying this probability to the observed yield of Drell–Yan events at high mass.

The number of diphoton events in the 100–160 GeV mass range is found to be 3650 ± 100 ± 290, where the first uncertainty is statistical and the second is systematic. The systematic uncertainty arises from the definition of the relaxed identification control region, the possible correlations between isolation and identification variables, and the fraction of real photons leaking into the background control regions. The extracted yields of photon-jet and dijet are 1110 ± 60 ± 270 and 220 ± 20 ± 130 events respectively. The Drell–Yan background, which is most prominent in the categories with at least one converted photon, is estimated to be 86 ± 1 ± 14 events in the mass range of 100–160 GeV.

Fig. 2 shows the extracted components of the diphoton, photon-jet, dijet and Drell–Yan processes. The purity of the sample (fraction of diphoton events) is about 72%. The measurement of the purity has also been made separately in each category, and ranges from 69% to 83%.

Other methods have been used to cross-check the purity estimate, in particular using template fits of the photon isolation distribution, where both signal and background templates are derived from data. The results are in agreement with the results quoted here.

5. Systematic uncertainties

Experimental systematic uncertainties affecting the extraction of the signal from the diphoton invariant mass distribution related to the modelling of the signal can be classified in two types: uncertainties affecting the predicted yield and uncertainties affecting the modelling of the mass resolution.

The uncertainties on the event yield are the following:

- The uncertainty from the photon reconstruction and identification efficiency amounts to ±11% per event. It is estimated from data and MC differences in shower shape variables, the impact of additional material in front of the calorimeter and the impact of pileup on the photon shower shape variables.
- The uncertainty on the isolation cut efficiency is taken as the difference between data and MC found in \( Z \to ee \) decays and amounts to ±3% per event.
- The uncertainty on the photon trigger efficiency is ±1%. It comes from the uncertainty in the measurement of the trigger efficiency for diphoton candidates using control triggers and from possible differences between the trigger efficiency for photons from Higgs boson decays and all diphoton candidates.
- The uncertainty on the kinematic cut acceptance from the modelling of the Higgs boson transverse momentum distribu-
tion is investigated with HQT [46] and RESBOS [47,48], which account for all-orders soft-gluon resummation up to NNLL accuracy. The resulting uncertainty is found to be at the level of ±1%.

- The luminosity uncertainty is 3.7% [15].

The total uncertainty on the expected signal event yield is ±12%.

The uncertainties on the invariant mass resolution are the following:

- The uncertainty on the cluster energy resolution comes from the uncertainty on the sampling term, estimated to be 10%, and from the uncertainty on the constant term, which is estimated using $Z \rightarrow ee$ decays. Both uncertainties are taken into account with their proper correlation from the $Z$ control sample constraint. The uncertainty on the cluster energy resolution amounts to a ±12% relative uncertainty on the diphoton invariant mass resolution.

- The uncertainty on the photon energy calibration arising from the extrapolation of the electron energy scale calibration is estimated from MC studies. The difference between the photon and the electron response in the calorimeter comes from the material in front of the active part of the calorimeter. The uncertainty is estimated using simulations with a different amount of material in front of the calorimeter and is found to be ±6% on the mass resolution.

- The contribution of pileup fluctuations to the cluster energy measurement is checked using random clusters in randomly triggered bunch crossings, with a frequency corresponding to expectations from the instantaneous luminosity. The relative uncertainty on the mass resolution is found to be less than 3%.

- The uncertainty on the resolution of the photon angle measurement is studied with $Z \rightarrow ee$ decays. The calorimeter-based direction measurement is compared with the much more precise track-based direction measurement. In the barrel calorimeter, the resolution measured in data agrees well with the one predicted by the simulation. In the end-cap region, the resolution measured in data is ≈20% worse than in the simulation. The impact of this difference is a 1% relative uncertainty on the diphoton mass resolution.

The total relative uncertainty on the diphoton invariant mass resolution is thus ±14%. This systematic uncertainty is applied to both the Crystal Ball and the wide Gaussian resolution parameters.

These systematic uncertainties are taken as fully correlated between the different categories. The impact of uncorrelated systematic uncertainties in the different categories and migration between categories has been investigated and found to be negligible.

The background is modelled by an exponentially falling invariant mass distribution. The impact of uncorrelated systematic uncertainties described in Section 5 and the uncertainty on the distribution which have Gaussian constraints in the fit. The uncertainty on the predicted event yield includes both the experimental systematic uncertainties described above, one per category, fixing the fraction of events in each category to the MC predictions. Table 2 summarises the measured fractions of background events in each category, the predicted fractions of signal events and the predicted core Gaussian mass resolutions for a Higgs boson mass hypothesis of 120 GeV.

The fitted parameters for the signal are thus the overall signal strength relative to the Standard Model prediction and the nuisance parameters on the predicted event yield and mass resolution which have Gaussian constraints in the fit. The uncertainty on the predicted event yield includes both the experimental systematic uncertainties described in Section 5 and the uncertainty on the predicted cross-section described in Section 3. The systematic uncertainty on the background shape is included as another nuisance parameter with a Gaussian constraint in the fit. From this fit, the best estimate of the signal yield is extracted, as well as the likelihood ratio (profile likelihood) between any assumed signal yield (leaving the nuisance parameters free to maximise the likelihood) and the best estimate. The fit is performed in 1 GeV steps for the Higgs boson mass hypothesis, which is significantly smaller than the invariant mass resolution. The signal parameters for these fine mass steps are interpolated from the fully simulated samples.

Fig. 3 shows the reconstructed diphoton mass spectrum. No excess is visible. This is quantified by the $p$-value of the background-only hypothesis, which gives the fraction of background-only experiments that would have a profile likelihood ratio of the zero signal hypothesis relative to the best-fitted signal strength at least as low as the one found in the data. Negative signal is not allowed in the fit, so $p$-values above 0.5 are truncated. This $p$-value is shown in Fig. 4(a) as a function of the hypothesised Higgs boson mass. The minimal $p$-value, corresponding to the largest back-

ground upward fluctuation, is ≈5% and is found for a hypothesised mass of ≈128 GeV. The probability for such an excess to appear anywhere in the investigated mass range is around 40%.

Exclusion limits on the inclusive production cross-section of a Standard Model Higgs boson relative to the Standard Model cross-section are derived. For this purpose, a modified frequentist approach $CL_s$ [52], corresponding to the ratio of $p$-values for the signal-plus-background and the background-only hypothesis for a given assumed signal strength is used. A given signal strength is excluded at 95% confidence level if its $CL_s$ is smaller than 0.05. The $CL_s$ confidence levels are computed using a large number of signal-plus-background and background-only pseudo-experiments, with different signal yields, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF, Austria; ANAS, Azerbaijan; STFC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DRSRC and Lundbeck Foundation, Denmark; ARTEMIS, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSA, Georgia; BMBF, DFG, MPG and AvH Foundation, Germany; GSKT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCUK, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERSYS (MIETCS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MST, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (UK) and BNL (USA) and in the Tier-2 facilities worldwide.
