Measurements of wavelength dependent scattering and backscattering coefficients by low-coherence spectroscopy

Nienke Bosschaart
Dirk J. Faber
Ton G. van Leeuwen
Maurice C. G. Aalders
In this study, we use LCS to quantitatively and simultaneously measure scattering \( \mu_s \) and backscattering \( \mu_b \) coefficients on a wide range of scattering media (\( \mu_s = 1 \) to 34 mm\(^{-1}\) and \( \mu_b = 2.10^{-6} \) to 2.10\(^{-3}\) mm\(^{-1}\)). Thereby, we demonstrate new opportunities for noninvasive scattering property measurements. 

In vivo measurements of the quantitative value of \( \mu_s \) and \( \mu_b \) can assist in differentiating between tissue types\(^2\) and modeling of light-tissue interactions. The spectrally resolved information of \( \mu_s \) and \( \mu_b \) gives additional valuable information such as the power dependency of \( \mu_b \) on wavelength and wavelength dependent oscillations in \( \mu_b \), which have shown to be related to tissue morphology\(^3,4\).

Whereas extensive study on tissue (back)scattering has been performed in the areas of light scattering spectroscopy\(^3\) and angle-resolved low-coherence interferometry,\(^1\) these studies lack quantification of \( \mu_s \) and \( \mu_b \); since their primary aim has been to retrieve the size of the scattering particles. Quantification of \( \mu_s \) and \( \mu_b \) has been shown in optical coherence tomography studies,\(^2,5\) but these studies were limited to the measurement of \( \mu_s \) and \( \mu_b \) averaged over the bandwidth of the spectrum, i.e., no spectral information was obtained. Moreover, in these studies, quantitative agreement with theory is rarely obtained for highly scattering media, due to multiple scattering contributions to the signal.\(^5\) Other (diffuse) reflectance spectroscopy techniques are able to measure \( \mu_s \) and the reduced scattering coefficient \( \mu_s'\),\(^6\) but this requires additional information on the scattering anisotropy \( g \) to obtain \( \mu_s \). Thus, compared to the existing methods for scattering property measurements, LCS offers the unique possibility for a combination of simultaneous, quantitative, and spectrally resolved measurement of \( \mu_s \) and \( \mu_b \). Therefore, these measurements will assist in a more complete, and likely more accurate, characterization of the tissue of interest. In addition, like other low coherence interferometry techniques,\(^2,5,7\) LCS measures a controlled and confined volume, which is important when measuring local optical properties in an often inhomogeneous tissue.

Using LCS, we measured \( \mu_b \) and \( \mu_s \) of aqueous nonabsorbing suspensions of different sized polystyrene spheres and validated our results with Mie theory. Therefore, we measured backscattered power spectra \( S(\ell) \) at controlled geometrical path lengths \( \ell \) of the light in a sample. Our LCS system, which is described in detail in Ref. 1, consists of a Michelson interferometer and is optimized for 480 to 700 nm. The geometrical round trip path length \( \ell \) (\( \ell = 0 \) to 2 mm, with \( \ell = 0 \) the sample surface) is controlled by translating the reference mirror, in steps of 27 \( \mu \)m. By translating the sample, focus tracking of the 64 \( \mu \)m\(^2\) spot size in the sample is achieved. Around \( \ell \), the signal is modulated by scanning the piezo-driven reference mirror (23 Hz) resulting in a scanning window of \( \Delta \ell \approx 44 \mu \)m. The optical power at the sample is 6 mW.

A multimode fiber (\( \phi = 62.5 \mu \)m) guides the reflected light from both arms to a photodiode. Signal processing after acquisition, which is described in detail in Ref. 1, results in averaged spectra \( S(\ell) \) with 8-nm resolution [\( \sim500 \) averaged per \( \ell \), to avoid any spectral modulations on \( S(\ell) \) caused by interference between scattering particles]. We describe \( S(\ell) \) with a single exponential decay model (Ref. 2) \( S(\ell) = S_0 \cdot T \cdot \Delta \ell \cdot \mu_{B, NA} \cdot \exp(-\mu_s \cdot \ell)^2 \) where \( S_0 \) is the source

\[ S_0 = \frac{P_0}{S_0} \cdot T \cdot \Delta \ell \cdot \mu_{B, NA} \cdot \exp(-\mu_s \cdot \ell)^2 \]
power spectrum and \( \mathbf{T} \) is the system coupling efficiency. When \( S(\xi) \) is dominated by a single backscattered light, \( \mu_s \) is the attenuation coefficient of the sample and \( \mu_b \) equals \( \mu_s \) for nonabsorbing samples (this study). The system dependent parameters will be denoted by \( \xi = S_0 \cdot \mathbf{T} \cdot \Delta \xi \). The spectra \( S(\xi) \) are collected over the detection numerical aperture (NA) of the system, therefore, we define the measured backscattering coefficient \( \mu_{b, \text{NA}} \) as the product of \( \mu_b \) and the phase function \( p(\theta) \), integrated over the solid angle of the NA in the medium:

\[
\mu_{b, \text{NA}} = \mu_b \cdot 2\pi \int_{\theta = \text{NA}}^{\pi} p(\theta) \cdot \sin(\theta) \cdot d\theta.
\]

We measured the wavelength dependent point spread function in the medium\(^7\) and derived the NA (ranging from 0.035 to 0.045 between 480 to 700 nm) from the resulting Rayleigh length of the system. The terms \( \xi \cdot \mu_{b, \text{NA}} \) and \( \mu_b \) are obtained by fitting a two-parameter (amplitude and decay, respectively) exponential function to \( S(\xi) \) versus \( \xi \). Uncertainties are estimated by the 95\% confidence intervals (c.i.) of the fitted parameters.\(^1\) The model is fitted to the measured \( S(\xi) \) up to a path length in the sample of five times the mean free path (5\( \mu_b \) from Mie theory at 480 nm, varying from 100 to 1950 \( \mu_m \)). Spectra acquired from \( \xi < 50 \mu_m \) suffer from boundary artifacts and are therefore excluded from the fits. Prior to fitting the model to \( S(\xi) \), a noise level is subtracted from \( S(\xi) \), which is the sum of the dc spectra of the sample and reference arm. Now, \( \mu_{b, \text{NA}} \) can be calculated from the fitted amplitude \( \xi \cdot \mu_{b, \text{NA}} \) if \( \xi \) is determined in a separate calibration measurement in which \( \mu_{b, \text{NA}} \) is exactly known from Mie theory and Eq. (1). To this end, we used National Institute of Standards and Technology (NIST)-certified polystyrene spheres of \( \phi = 409 \pm 9 \) nm (diameter \pm SD, Thermo Scientific, USA). The obtained \( \xi \) was used to determine \( \mu_{b, \text{NA}} \) in subsequent measurements.

In our Mie calculations, we used wavelength dependent refractive indices of water and polystyrene\(^6\) and integrated over the size distribution of the spheres (2\( \delta \)SD), given by the manufacturer. Brownian motion of the polystyrene spheres causes Doppler broadening of the measured LCS spectra. For adequate comparison, we convolved the Mie spectra with a Lorentzian, with a linewidth of 5 to 13 nm, depending on the size dependent Doppler frequency distribution of the Brownian motion of the spheres, similar to our analysis in Ref. 1.

Figure 1(a) shows LCS measurements (dots) of \( \mu_b \) for four aqueous suspensions of different sized NIST-certified polystyrene spheres: 0.071% with \( \phi = 409 \pm 9 \) nm, 0.048% with \( \phi = 602 \pm 6 \) nm, 0.038% with \( \phi = 799 \pm 9 \) nm, and 0.033% with \( \phi = 1004 \pm 10 \) nm, which lie within the range of scatterer sizes in biological cells.\(^7\) The sphere concentrations, indicated in volume percentages, were chosen such that \( \mu_b \) was approximately equal for all samples (~1.5 mm\(^{-1}\) at 600 nm). The LCS measurements agree within 0.2 mm\(^{-1}\) with \( \mu_b \) from Mie theory (thick solid lines) over the entire wavelength range of 480 to 700 nm. The scattering coefficient has a power dependence on wavelength, with different scatter power for different particle sizes. We also measured the attenuation coefficient of water, which, as expected, is ~0 mm\(^{-1}\) for all wavelengths.

Figure 1(b) shows the LCS measurements (dots) of \( \mu_{b, \text{NA}} \) on a logarithmic scale for the polystyrene suspensions, after measuring \( \xi \) on the 409-nm sample. The error bars in this graph are on the same order of magnitude as the marker size. The \( \mu_{b, \text{NA}} \) differ over an order of magnitude between samples, since the phase function changes considerably with sphere size. The measured \( \mu_{b, \text{NA}} \) are in agreement with Mie theory (thick solid lines), showing the characteristic sphere size dependent oscillations. The \( \mu_{b, \text{NA}} \) of water shows no pronounced spectral features, which implies that our calibration method was applied correctly. We attribute the small differences between measurements and Mie calculations to uncertainties in particle size distribution and refractive index that were used as Mie-input (depending on wavelength, a 1% change in the polystyrene refractive index results in a 11 to 14% change in \( \mu_b \) and a 11 to 25% change in \( \mu_{b, \text{NA}} \)).

To test the range of validity of the single exponential decay model to obtain \( \mu_b \) and \( \mu_{b, \text{NA}} \), it is important to also test the model for media with higher scattering densities. Therefore, we increased the particle concentration for the 409 nm sample several times (from 0.071\% to 0.950\%) and measured \( \mu_b \) and \( \mu_{b, \text{NA}} \). Figure 2(a) shows that the measured \( \mu_b \) agrees with Mie calculations of \( \mu_b \) within 14\% , up to values as high as 34 mm\(^{-1}\), which lies well within the range of tissue scattering. In addition, the measured \( \mu_{b, \text{NA}} \) is in agreement with Mie theory [(Fig. 2(b)], except for the two highest volume concentrations, where the measurement overestimates \( \mu_{b, \text{NA}} \) at the shorter wavelengths.

The measurements of \( \mu_b \) in Figs. 1(a) and 2(a) demonstrate that disagreement with the Mie calculated values for the highest volume concentrations (Fig. 2) is only manifested in \( \mu_{b, \text{NA}} \) and not in \( \mu_b \) (i.e., \( \mu_b \) agrees with the Mie calculated \( \mu_b \) within the 95\% c.i.). For these samples (0.533\% and 0.950\%), the average surface-to-surface distance between the spheres is comparable to the wavelength: 760 and 556 nm, respectively. Since the effect of multiple scattering would be visible in the measured value of both coefficients, we speculate that another effect may cause this disagreement, i.e., the total scattered field cannot be treated as the superposition of the scattered field by the individual particles (dependent scattering).\(^3\) Our results indicate that for these sphere concentrations, \( \mu_{b, \text{NA}} \) is altered to favor more backward than forward directed scattering. Further study is needed to assess the influence of the particle phase function and interparticle distance on the measured \( \mu_b \) and \( \mu_{b, \text{NA}} \).

---

**Fig. 1** LCS (dots) and Mie (thick solid lines) results for (a) scattering coefficients \( \mu_b \) and (b) backscattering coefficients \( \mu_{b, \text{NA}} \) for four aqueous suspensions of different sized polystyrene spheres and water. Error bars, representing the 95\% c.i. of the fitted values, may fall behind data points. The \( \mu_{b, \text{NA}} \) were calibrated using the 409-nm sample.
to measure in nonlayered, homogeneous samples, LCS has the potential to be corrected for tissue absorption. Several methods to separate scattering and absorption contributions to the LCS signal, since the \( \mu_t \) contains information on tissue tissue optics.

The presented results show that LCS enables sample characterization based on absolute values of \( \mu_{t,NA} \) and \( \mu_b \), the scatter power in \( \mu_t \) and oscillations in \( \mu_{b,NA} \). This very combination of optical properties is characteristic for particle or tissue type\(^{2-7} \)

In nonabsorbing samples, \( \mu_b \), is extracted directly from the measurement and \( \mu_{b,NA} \) requires calibration on a sample with known \( \mu_{t,NA} \). To obtain \( \mu_t \) from tissue, the measured \( \mu_t \) needs to be corrected for tissue absorption. Several methods to separate \( \mu_t \) and \( \mu_b \) from a single attenuation profile have been proposed.\(^{11,12} \) In addition, the simultaneous measurement of both \( \mu_t \) and \( \mu_{b,NA} \) by LCS may eventually assist in separating scattering and absorption contributions to the LCS signal, since the \( \mu_{b,NA} \) is proportional to \( \mu_t \) but independent of \( \mu_b \).

Whereas in this study, the scattering properties are measured in nonlayered, homogeneous samples, LCS has the potential to measure \( \mu_t \) and \( \mu_{b,NA} \) in individual layers of layered media such as human skin. The controlled path length and the confined measurement volume due to the confocality of the system, in principle, allow to measure within a layer of choice, which will be a subject of further study. Even for a confined tissue volume, the \( \mu_{b,NA} \) is likely to consist of the contribution of a range of scatterer sizes and therefore, it will not exhibit oscillations as clearly presented in Figs. 1 and 2. Nevertheless, tissue specific spectral features in backscattering have been observed\(^{13,14} \) and also the absolute value of \( \mu_{b,NA} \) contains information on tissue type.\(^{2} \)

In conclusion, we present quantitative and wavelength dependent measurements of scattering and backscattering coefficients from polystyrene sphere suspensions. Our method applies for a broad range of sphere sizes and particle densities, and is in excellent agreement with Mie theory up to scattering coefficients as high as 34 nm\(^{-1} \). LCS measures \( \mu_t \) and \( \mu_b \) simultaneously, over a large wavelength range and with good spectral resolution. The combined wavelength dependent information of \( \mu_t \) and \( \mu_b \) is likely to assist in more accurate tissue characterization in tissue optics.
