Abstract. Localized spectroscopic measurements of optical properties are invaluable for diagnostic applications that involve layered tissue structures, but conventional spectroscopic techniques lack exact control over the size and depth of the probed volume. We show that low-coherence spectroscopy (LCS) overcomes these limitations by measuring local attenuation and absorption coefficient spectra in layered phantoms. In addition, we demonstrate the first in vivo LCS measurements of the human epidermis and dermis only, from the measured absorption in two distinct regions of the dermal microcirculation, we determine total hemoglobin concentration (3.0 ± 0.5 g/l and 7.8 ± 1.2 g/l) and oxygen saturation. © 2011 Society of Photo-Optical Instrumentation Engineers (SPIE). The derivation of physiological parameters from the spectroscopic determination of tissue optical properties can offer a fast and painless alternative to invasive diagnostic procedures such as tissue biopsies and drawing of blood. For instance, the absorption coefficient of the dermal microcirculation is directly related to the tissue hemoglobin concentration, which provides information on oxygen saturation, blood volume, and potentially the hemoglobin concentration in whole blood. A variety of spectroscopic techniques is available for measuring tissue optical properties. However, these techniques have limited ability to confine their probing volume to embedded structures such as the dermal microcirculation (located beneath the epidermis), or require long photon path lengths (several mm to cm) which exceed the adult dermal thickness (± 0.2 – 1.2 mm). Consequently, many of those techniques rely on assumption-based algorithms to account for layered media. Low-coherence interferometry techniques, such as low-coherence spectroscopy (LCS) and spectroscopic optical coherence tomography (sOCT) do not suffer from this limitation, since they control the size and position of the probed volume from which the optical properties are determined (lateral and in depth)—i.e., they reject the detection of photons that originate from outside the volume of interest.

We recently validated LCS on homogeneous phantoms with controlled optical properties, to quantitatively obtain the attenuation μa, absorption μs, scattering μs, and backscattering μb coefficients between 480 and 700 nm [bold-faced characters denote wavelength (λ) dependent parameters]. In this study we present, for the first time to our knowledge, quantitative measurements of local μs and μa spectra within selected volumes of inhomogeneous turbid media. We validate our method by retrieving the dye concentration from the measured μa of an Intralipid-dye phantom (μa = 4 to 6 mm−1, μa = 0 to 5 mm−1), covered by light attenuating layers with varying optical densities (0.39 to 0.89). Subsequently, we demonstrate the first in vivo LCS measurements of μs and μa of the human epidermis and dermal microcirculation, from which we determine total hemoglobin concentrations and oxygen saturation.

To obtain μs and μa from a target volume, we measured backscattered power spectra S(ℓ) at controlled geometrical path lengths ℓ of the light in the medium (path length and depth related parameters are corrected for the refractive index n of the medium). Our LCS system, which is described in detail in Ref. 5, is optimized for the wavelength range of 480 to 700 nm. We controlled ℓ by translating the reference mirror in steps of 27 μm. By translating the sample in the axial direction, focus tracking by translating the reference mirror (23 Hz), resulting in a scanning window of ∆ℓ ≈ 44 μm in the medium. The optical power at the sample is 6 mW.

A multimode fiber (φ = 62.5 μm) guides the reflected light from both arms to a photodiode. Fourier transformation of the acquired time signal results in spectra S(ℓ) with spectral resolution Δλ = λ2/(nΔν) (4 nm < Δλ < 9 nm). To minimize the influence of speckle noise on S(ℓ), we spatially average 90 to 250 spectra by translating the sample and measuring S(ℓ) every 5 μm. Fitting the single exponential decay model S(ℓ) = A · exp(−μ · ℓ) (free running fit parameters A and μ) to the background corrected S(ℓ) versus ℓ, results in a μs spectrum. Uncertainties in A and μs are estimated by their 95% confidence intervals (c.i.).

When S(ℓ) is dominated by single backscattered light, the attenuation coefficient μs = μa + μb. Since the dependence of μs on wavelength can be described by a · λ−b, least-squares fitting of μs = a · λ−b + Σi (ci · μai) results in the individual contributions of μai and μbi to the measured μs. The free running fit parameters ai, bi, and ci are constraint to positive values. The wavelength dependent μai are the known absorption spectra (unit: mm−1 per unit concentration) of the contributing chromophores i with contribution ci, which are μai of the dye for the phantom measurements and μai of deoxygenized hemoglobin (Hb) and oxygenized hemoglobin (HbO2) for the in vivo skin measurements. The μa of the dye was obtained from a...
tering layers varied in thickness. Lateral averaging and the uncertainty estimates (±95% c.i.) for the \( \mu_t \) and the \( \mu_s \) contributions to the \( \mu_t \)-fits are shown for all measurements. measured values, indicating that the measurement of \( \mu_t \) is unaffected by the optical density of the layer covering the medium. Therefore, we support our analysis by reconstructing an OCT image from the individual LCS time signals within every \( \Delta \xi \) in the axial and lateral direction, using depth scaling \( d = \xi/\Delta \). The axial resolution of these “fused” OCT images is given by the coherence length of the light source of \( \sim 1.5 \mu m \) and is therefore higher than the axial resolution of 22 \( \mu m \) for \( S(\xi) \). Figure 1 shows the measured \( \mu_t \) (dots) of a medium consisting of 1% Intralipid (Intralipid\textsuperscript{®} 20%, Fresenius Kabi, Germany) and 10% magenta dye (Ecoline #337, Royal Talens, The Netherlands), uncovered and covered by nonabsorbing silicon-titanium dioxide (TiO\textsubscript{2}) layers. The three covering layers varied in thickness \( D \) and scattering (layer 1: \( D = 155 \mu m, \mu_s = 2.5 \text{ mm}^{-1}; \) layer 2: \( D = 170 \mu m, \mu_s = 5 \text{ mm}^{-1}; \) layer 3: \( D = 355 \mu m, \mu_s = 2.5 \text{ mm}^{-1} \)). The fitted \( \mu_t \) and \( \mu_s \)-contributions to the \( \mu_t \)-fits are shown for all measurements. Since we are primarily interested in the total hemoglobin concentration (\([tHb] = cHbO2 + cHb\)) and the oxygen saturation (\(SO2 = \frac{cHbO2}{[tHb]}\)) with their uncertainty estimates (±95% c.i.) for the \textit{in vivo} measurements, we directly fit the \([tHb]\) and the \(SO2\) by substituting \(cHbO2\). Transmission measurement. Since we are primarily interested in the total hemoglobin concentration (\([tHb] = cHbO2 + cHb\)) and the oxygen saturation (\(SO2 = \frac{cHbO2}{[tHb]}\)) with their uncertainty estimates (±95% c.i.) for the \textit{in vivo} measurements, we directly fit the \([tHb]\) and the \(SO2\) by substituting \(cHbO2\). The volume from which we obtain \(\mu_t\) is controllable in both size and position inside the medium, by choosing the region for lateral averaging and the \(\xi\)-interval for fitting the exponential decay model. When measuring on inhomogeneous media such as skin, spatial information is needed to confine our region of interest to, e.g., the epidermal or dermal layer. Therefore, we support our analysis by reconstructing an OCT image from the individual LCS time signals within every \(\Delta \xi \) in the axial and lateral direction, using depth scaling \( d = \xi/\Delta \). The axial resolution of these “fused” OCT images is given by the coherence length of the light source of \( \sim 1.5 \mu m \) and is therefore higher than the axial resolution of 22 \( \mu m \) for \( S(\xi) \).

acquisition, the latter will require correction for unwanted signal attenuation due to out-of-focus detection and sensitivity roll-off in depth.8,12

Potentially, the dermal [tHb] can be related to the hemoglobin concentration in whole blood, if the blood volume within the investigated region can be assessed. A possible method that deserves further investigation for this purpose is obtaining the blood volume from the OCT image by assessing the vessel density using advanced signal analysis, for instance as described in Ref. 11. When measuring other tissue types, the contribution of additional chromophores (e.g., bilirubin, melanin) to the measured \( \mu_t \) may need to be incorporated in our analysis. Also, a correction for Doppler broadening or shifting of the measured \( \mu_t \) spectra may be needed for tissues that exhibit blood flow. We did not observe any of those influences on the measured \( \mu_t \) spectra in Fig. 2(b), which can be explained by a temporary decrease of blood flow due to applied pressure on the skin.

In conclusion, we have shown that we can use LCS to locally obtain absorption coefficient spectra within confined volumes of optically inhomogeneous media. This enabled us to perform the first \( \textit{in vivo} \) LCS measurements of hemoglobin concentration and oxygen saturation inside the dermal microcirculation. By confining the measurement volume to specific tissue structures, LCS overcomes the limitations of conventional spectroscopic techniques. LCS therefore offers a potential alternative to invasive drawing of blood for the determination of whole blood hemoglobin concentration and oxygen saturation.
