Measurement of the production cross-section of a single top quark in association with a $W$ boson at 8 TeV with the ATLAS experiment

The ATLAS collaboration

E-mail: atlas.publications@cern.ch

ABSTRACT: The cross-section for the production of a single top quark in association with a $W$ boson in proton-proton collisions at $\sqrt{s} = 8$ TeV is measured. The dataset corresponds to an integrated luminosity of 20.3 fb$^{-1}$, collected by the ATLAS detector in 2012 at the Large Hadron Collider at CERN. Events containing two leptons and one central $b$-jet are selected. The $Wt$ signal is separated from the backgrounds using boosted decision trees, each of which combines a number of discriminating variables into one classifier. Production of $Wt$ events is observed with a significance of 7.7$\sigma$. The cross-section is extracted in a profile likelihood fit to the classifier output distributions. The $Wt$ cross-section, inclusive of decay modes, is measured to be $23.0 \pm 1.3$ (stat.)$^{+3.3}_{-2.2}$ (syst.)$\pm 1.1$ (lumi.) pb. The measured cross-section is used to extract a value for the CKM matrix element $|V_{tb}|$ of $1.01 \pm 0.10$ and a lower limit of 0.80 at the 95% confidence level. The cross-section for the production of a top quark and a $W$ boson is also measured in a fiducial acceptance requiring two leptons with $p_T > 25$ GeV and $|\eta| < 2.5$, one jet with $p_T > 20$ GeV and $|\eta| < 2.5$, and $E_T^{\text{miss}} > 20$ GeV, including both $Wt$ and top-quark pair events as signal. The measured value of the fiducial cross-section is $0.85 \pm 0.01$ (stat.)$^{+0.06}_{-0.06}$ (syst.)$\pm 0.03$ (lumi.) pb.

1 Introduction

The production of a single top quark at the Large Hadron Collider (LHC) proceeds via
the weak interaction in the Standard Model (SM). The three main modes of single top-
quark production are: t-channel, the exchange of a W boson between a light quark and
a heavy quark; s-channel, via a virtual W boson; and Wt, the production of a top quark
in association with a W boson. Single top-quark production depends on the top-quark
coupling to the W boson, which is parameterised by the form factor $f_{LV}$ and the Cabibbo-
Kobayashi-Maskawa (CKM) matrix element $V_{tb}$ \cite{1-3}. The cross-section for each of
the three production modes is proportional to the square of $|f_{LV}V_{tb}|$ \cite{4, 5}. Physics beyond
the SM can contribute to the single top-quark final state and modify the production cross-
sections \cite{6, 7} as well as the kinematic distributions, for example through a resonance that
decays to Wt \cite{8, 9}.
The production of single top quarks has been observed at the Tevatron proton-antiproton collider in the $t$-channel [10, 11] and $s$-channel [12–14], as well as their combination [15–17]. The $Wt$ process has a small expected cross-section at the Tevatron and was not observed. The $t$-channel mode has been observed by both the ATLAS [18, 19] and CMS [20, 21] collaborations at the LHC. The $s$-channel mode has not yet been measured at the LHC because of its small production cross-section [22]. Evidence for $Wt$ production was reported by ATLAS [23] and CMS [24] in proton-proton ($pp$) collisions at 7 TeV. The observation of $Wt$ production in $pp$ collisions at 8 TeV has been reported by CMS [25].

Production of $Wt$ events proceeds via $b$-quark-induced partonic channels such as $gb \rightarrow Wt \rightarrow W^- W^+ b$. A leading-order (LO) Feynman diagram in the 5-flavour-number scheme (5FNS, considering the quarks $u$, $d$, $s$, $c$, and $b$ in the initial state) is shown in figure 1. The presence of only a single $b$-quark in the final state represents a distinctive feature with respect to the $W^+ W^- b b$ final state of top-quark pair ($tt$) production. The $Wt$ final state contains an additional $b$-quark in higher-order Quantum Chromodynamics (QCD) correction diagrams in the 5FNS, as well as in the leading-order process in the 4-flavour-number scheme (4FNS, considering only the quarks $u$, $d$, $s$, $c$ in the initial state), making it challenging to experimentally separate $Wt$ production from $tt$ production.

The theoretical prediction for the $Wt$ production cross-section at next-to-leading order (NLO) with next-to-next-to-leading logarithmic (NNLL) soft gluon corrections is $22.37 \pm 1.52$ pb [26] at a centre-of-mass energy of $\sqrt{s} = 8$ TeV for a top-quark mass of $m_t = 172.5$ GeV [27]. In this calculation, the uncertainty on the theoretical cross-section accounts for the variation of the renormalisation and factorisation scale between $m_t/2$ and $2m_t$ and for the parton distribution function (PDF) uncertainties (using the 90% confidence level errors of the MSTW2008 NNLO PDF set [28]). This cross-section represents about 20% of the total cross-section for all single top-quark production modes at the LHC. A second theoretical prediction for the $Wt$ production cross-section is $18.8 \pm 0.8$ (scale) $\pm 1.7$ (PDF) pb, computed at NLO with Hathor v2.1 [29, 30]. The PDF uncertainties are calculated using the PDF4LHC prescription [31] with three different PDF sets (CT10, MSTW2008NLO68CL [28] and NNPDF2.3 [32]). The renormalisation and factorisation scales are set to 65 GeV and the $b$-quark from initial-state radiation is required to have a transverse momentum of less than 60 GeV.

This paper presents a measurement of the cross-section for $Wt$ production in $pp$ collisions at $\sqrt{s} = 8$ TeV, based on the analysis of $20.3 \text{fb}^{-1}$ of data collected by the ATLAS
detector in 2012. The measurement is carried out in the dilepton final state shown in figure 1 where each W boson decays to an electron or a muon and a neutrino (eν or μν). This analysis requires two opposite-sign high-transverse-momentum (p_T) leptons (ee, eμ, μμ), missing transverse momentum (E_T^{miss}), and one high-p_T central jet, which is required to contain a b-hadron (b-jet). The main background to this signature is from t̅t̅ production, with smaller backgrounds coming from dibosons (WW, WZ, ZZ), Z+jets, and events where one or both leptons are misidentified (fake-lepton events) or non-prompt. Control regions enriched in t̅t̅ and other background events are also defined. Events in the t̅t̅-enriched regions fulfil the same lepton and missing transverse momentum requirements, and have exactly two jets, with one or both of the jets required to be identified as a b-jet. Events in the other background-enriched regions have one or two jets which are required to not be identified as b-jets. The backgrounds are estimated with simulation, except the non-prompt or fake-lepton background, which is estimated from data. Boosted decision trees (BDT) are used to optimise the discrimination between signal and background [33]. The cross-section is extracted using a profile likelihood fit of the BDT response. The background normalisation and the systematic uncertainties are constrained by simultaneously analysing phase-space regions with substantial Wt signal contributions and regions where the Wt contributions are negligible. The ratio of the measured cross-section to the theoretical prediction (which assumes V_{tb} = 1) is used to extract a value of |f_{LV}V_{tb}|.

In the 5FNS, the Wt single top-quark process overlaps and interferes with t̅t̅ production at NLO where diagrams involving two top quarks are part of the real emission corrections to Wt production [34, 35]. A calculation in the 4FNS scheme includes Wt and t̅t̅ as well as non-top-quark diagrams [36] and the interference between Wt and t̅t̅ enters already at tree level. A measurement of the cross-section inside a fiducial acceptance, designed to reduce the dependence on the theory assumptions, is also presented. The fiducial acceptance is defined using physics objects constructed of stable particles to approximate the Wt detector acceptance. The cross-section for the sum of Wt and t̅t̅ production is measured in this fiducial acceptance.

This paper is organised as follows: section 2 provides a brief overview of the ATLAS detector and the definition of physics objects. Section 3 describes the data and Monte Carlo samples used for the analysis. Section 4 describes the event selection and background estimation. Section 5 presents the procedure defined to discriminate the signal from the backgrounds using BDTs. The dominant systematic uncertainties are discussed in section 6. Section 7 presents the results for the inclusive cross-section measurement and for |V_{tb}| and discusses the impact of systematic uncertainties. Section 8 defines the fiducial acceptance and presents the fiducial cross-section measurement. Finally, a summary is presented in section 9.

2 The ATLAS detector and object reconstruction

The ATLAS detector [37] is a multi-purpose particle detector with a forward-backward symmetric cylindrical geometry and a near 4π coverage in solid angle.\footnote{ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the centre of the detector and the z-axis along the beam pipe. The x-axis points from the IP to the centre} ATLAS comprises
an inner detector (ID) surrounded by a thin superconducting solenoid providing a 2 T axial magnetic field, a calorimeter system and a muon spectrometer in a toroidal magnetic field. The ID tracking system covers the pseudorapidity range $|\eta| < 2.5$ and consists of silicon pixel, silicon microstrip, and transition radiation tracking detectors. The ID provides precise position and momentum measurements for charged particles and allows efficient identification of jets containing $b$-hadrons. Lead/liquid-argon (LAr) sampling calorimeters provide electromagnetic (EM) energy measurements with high granularity up to $|\eta| = 2.5$. A hadron (steel/scintillator-tile) calorimeter covers the central pseudorapidity range ($|\eta| < 1.7$). The end-cap and forward regions are instrumented with LAr calorimeters for both the EM and hadronic energy measurements up to $|\eta| = 4.9$. The muon spectrometer surrounds the calorimeters. It consists of three large air-core toroid superconducting magnet systems, separate trigger detectors and high-precision tracking chambers providing accurate muon tracking for $|\eta| < 2.7$ and muon triggering for $|\eta| < 2.4$.

A three-level trigger system [38] is used to select events. The first-level trigger is implemented in hardware and uses a subset of the detector information to reduce the event rate to less than 75 kHz. Two software-based trigger levels, Level-2 and the Event Filter, reduce the rate of Level-1 accepts to about 400 Hz on average.

Candidate events are characterised by exactly two leptons ($ee$, $\mu\mu$, $e\mu$), missing transverse momentum $E_T^{miss}$ due to the neutrinos from the leptonic decays of the two $W$ bosons, and a $b$-jet originating from the top-quark decay. Electron candidates are reconstructed from energy clusters in the calorimeter which are matched to ID tracks [39]. Selected electrons must have $E_T > 25$ GeV and $|\eta| < 2.47$, excluding the barrel/end-cap transition region of $1.37 < |\eta| < 1.52$. A hit in the innermost layer of the ID is required, to reject photon conversions. Electron candidates are required to fulfil calorimeter-based and track-based isolation requirements in order to suppress backgrounds from hadron decays. The calorimeter transverse energy within a cone of size $\Delta R = 0.2$ and the scalar sum of track $p_T$ within $\Delta R$ of $0.3$ around the electron, in each case excluding the contribution from the electron itself, are each required to be smaller than $E_T$- and $\eta$-dependent thresholds calibrated to give nominal selection efficiencies of $90\%$ for prompt electrons from $Z \rightarrow ee$ decays.

Muon candidates are reconstructed by combining matching tracks reconstructed in both the ID and the muon spectrometer [40]. Selected muons have a $p_T > 25$ GeV and $|\eta| < 2.5$. An isolation criterion [41] is applied in order to reduce background contamination from events in which a muon candidate is accompanied by hadrons. The ratio of the sum of $p_T$ of additional tracks in a variable-size cone around the muon, to the $p_T$ of the muon [41], is required to be less than 0.05, yielding a selection efficiency of $97\%$ for prompt muons from $Z \rightarrow \mu\mu$ decays.

Jets are reconstructed using the anti-$k_T$ jet clustering algorithm [42] with a radius parameter of $R = 0.4$, using locally calibrated topological clusters as inputs [43]. Jet energies are calibrated using energy- and $\eta$-dependent correction factors derived from simulation and with residual corrections from in-situ measurements [44]. Jets are required to be re-

\footnote{of the LHC ring, and the $y$-axis points upwards. Cylindrical coordinates $(r, \phi)$ are used in the transverse plane, $\phi$ being the azimuthal angle around the $z$-axis. The pseudorapidity is defined in terms of the polar angle $\theta$ as $\eta = - \ln \tan(\theta/2)$. Angular separation is measured in units of $\Delta R = \sqrt{(\Delta \eta)^2 + (\Delta \phi)^2}$.}
constructed in the range $|\eta| < 2.5$ and to have $p_T > 20$ GeV. To reduce the contamination due to jets from additional $pp$ interactions in the same or neighbouring bunch crossings (pileup), tracks originating from the primary vertex must contribute a large fraction to the scalar sum of the $p_T$ of all tracks in the jet. This jet vertex fraction (JVF) [45] is required to be at least 50% for jets with $p_T < 50$ GeV and $|\eta| < 2.4$.

To avoid double-counting objects in an event and to suppress leptons from heavy-flavour decays, overlaps between reconstructed objects are resolved in the following order: (1) jets overlapping with a selected electron within $\Delta R$ of 0.2 are removed; (2) electrons that are within $\Delta R$ of 0.4 of a jet are removed; (3) events are rejected if a selected electron shares an ID track with a selected muon; and (4) muons that are within $\Delta R$ of 0.4 of a jet are removed.

The identification of $b$-jets relies on the long lifetime of $b$-hadrons and the topological properties of secondary and tertiary decay vertices reconstructed within the jet. A combination of multivariate algorithms is used to identify $b$-jets ($b$-tag) [46]. The $b$-tag algorithm has an average efficiency of 70% for $b$-jets from $t\bar{t}$ decays and an average mis-tag rate of 0.8% [47, 48] for light-quark jets.

The missing transverse momentum ($E_T^{\text{miss}}$) is calculated as the magnitude of the vector sum over the energies of all clusters in the calorimeters, and is refined by applying object-level corrections to the contributions arising from identified electrons, muons, and jets [49].

3 Data and simulated samples

The dataset used for this analysis was collected at $\sqrt{s} = 8$ TeV in 2012 by the ATLAS detector at the LHC, and corresponds, after data quality requirements, to an integrated luminosity of 20.3 fb$^{-1}$. Events are required to have either a single-electron or single-muon trigger. The electron and muon triggers impose a $p_T$ threshold of 24 GeV, along with isolation requirements on the lepton. To recover efficiency for higher $p_T$ leptons, the isolated lepton triggers are complemented by triggers without isolation requirements, but with $p_T$ thresholds of 60 GeV and 36 GeV for electrons and muons respectively.

Samples of signal and background events are simulated using various Monte Carlo (MC) generators, as summarised in table 1. The generators used for the estimation of the modelling uncertainties are listed together with the reference simulation for the $Wt$ signal and the $t\bar{t}$ background. In addition, PDFs used by each generator and the perturbative order in QCD of the respective calculations are provided. All simulation samples are normalised to theoretical cross-section predictions. A top-quark mass of 172.5 GeV is used [27].

The $Wt$ events are simulated using the NLO generator POWHEG-BOX [50, 51], interfaced to PYTHIA [52] for parton showering with the Perugia 2011C set of tuned parameters [53]. In the POWHEG-BOX event generator, the CT10 [54] PDFs are used, while the CTEQ6L1 [55] PDFs are used for PYTHIA. The generation of $Wt$ events is performed in the 5FNS. The overlap and interference between $Wt$ and $t\bar{t}$ is handled using the diagram-removal scheme (DR), where all doubly resonant NLO $Wt$ diagrams are removed [56]. An additional sample, generated with the diagram-subtraction scheme (DS), where the cross-
Table 1. Monte Carlo generators used to model the $Wt$ signal and the background processes at $\sqrt{s} = 8$ TeV. The samples marked with a † are used as alternatives for $Wt$ or $t\bar{t}$ to evaluate modelling uncertainties. DR refers to the diagram-removal scheme and DS to the diagram-subtraction scheme to handle the overlap and interference between $Wt$ and $t\bar{t}$, as discussed in the text.

section contribution from Feynman diagrams containing two top quarks is subtracted, is used to evaluate the uncertainty associated with the modelling of the overlap between $Wt$ and $t\bar{t}$ [56]. Two alternative samples are used to determine theory modelling uncertainties: one using MC@NLO [57] and the other using Powheg-Box, both interfaced to Herwig [58], with Jimmy for underlying-event modelling [59].

The dominant and largely irreducible $t\bar{t}$ background is simulated with Powheg-Box, using the CT10 NLO PDF set, with parton showering and hadronisation performed with Pythia. The $t\bar{t}$ production cross-section is $\sigma_{tt} = 253^{+13}_{-15}$ pb, computed at NNLO in QCD, including resummation of NNLL soft gluon terms [60–66].

Smaller backgrounds arise from diboson and $Z+$jets production. The Alpgen LO generator [67], interfaced to Herwig, is used to generate diboson events, with the CTEQ6L1 PDF set. Diboson events are normalised to the NLO prediction [68]. The $Z+$jets background is generated with Alpgen, interfaced to Pythia, with the CTEQ6L1 PDF set. The diboson estimate also accounts for lower cross-section diboson processes, including $H \to WW$. The $Z+$jets events are normalised to the NNLO prediction [69].
The non-prompt or fake-lepton background arises from non-prompt electrons or muons from the weak decay of mesons events, or from events where one or both leptons are mis-identified. This background contribution includes the \( t \)-channel and \( s \)-channel single top-quark production modes. The normalisation and shape of the non-prompt or fake-lepton background is determined directly from data, using the matrix method [70]. In addition to events from the signal data sample (labelled as “tight” events), a second (“loose”) set enriched with fake leptons is defined by removing the lepton isolation requirement. Given the probabilities for real and fake leptons that already passed the loose selection to also pass the tight selection, the number of tight events with a fake lepton is determined from a linear system of equations.

Generated events are passed through a simulation [71] of the ATLAS detector based on \( \text{GEANT4} \) [72] and reconstructed using the same procedure as for collision data. The alternative \( \bar{t}t \) samples used to evaluate theory modelling uncertainties are instead processed with the \( \text{ATLFAST-II} \) [71] simulation, which employs a parameterisation of the response of the electromagnetic and hadronic calorimeters, and \( \text{GEANT4} \) for the other detector components. The simulations also include the effect of multiple \( pp \) collisions per bunch crossing (pileup).

4 Event selection

The dilepton selection requires that each event has a high-quality reconstructed primary vertex, which must be formed from at least five tracks with \( p_T > 0.4 \) GeV. Each selected event must contain exactly two isolated opposite-sign leptons (\( e, \mu \)) that originate from the primary vertex, at least one of which must be associated with a lepton that triggered the event. In addition, since the \( Wt \) signature contains a high-\( p_T \) quark from the top-quark decay, events are required to have either one jet or two jets.

Events from \( Z \)-boson decays (including \( Z \rightarrow ee, Z \rightarrow \mu\mu, \) and \( Z \rightarrow \tau\tau \) with \( \tau \rightarrow e \) or \( \mu \)) are suppressed through requirements on the invariant mass of the dilepton system as well as on \( E_T^{\text{miss}} \) and the pseudorapidity of the leptons+jet(s) system. Events containing same-flavour leptons (\( ee \) or \( \mu\mu \)) are rejected if the invariant mass of the lepton pair is between 81 GeV and 101 GeV. Events are also required to have \( E_T^{\text{miss}} > 40 \) GeV, with the threshold raised to 70 GeV if the invariant mass of the lepton pair is below 120 GeV. Events containing one electron and one muon are required to have \( E_T^{\text{miss}} > 20 \) GeV, with the threshold raised to 50 GeV if the invariant mass of the lepton pair is below 80 GeV. Since \( Wt \) events are more central than \( Z+\)jets events, the pseudorapidity of the system of both leptons and all jets, reconstructed from the vectorial sum of lepton and jet momenta, is required to be \(|\eta^{\text{sys}}| < 2.5\).

Events are categorised into five regions depending on the jet and \( b \)-tag multiplicities. The largest number of expected signal events is in the 1-jet region with one \( b \)-tagged jet, while events in the two-jet regions with one or two \( b \)-tags are dominated by \( \bar{t}t \). These three regions are included in the cross-section fit. Two additional regions are used to validate the modelling of the other backgrounds but are not included in the fit. One-jet and two-jet events that have zero \( b \)-tagged jets compose the 0-tag control regions, which are enhanced...

The predicted event yields for signal and backgrounds, and their uncertainties, are summarised in table 2. Uncertainties from different sources are added in quadrature, not taking into account possible correlations. Many of the sources of systematic uncertainty are common to the $Wt$ signal and $t\bar{t}$ background processes, and correlated between regions (see section 6). The numbers of events observed in data and the total predicted yields are compatible within the uncertainties. The $Wt$ signal comprises 21% of the total expected event yield in the 1-jet 1-tag region. The main background originates from the production of top-quark pair events, which accounts for almost 80% of the total event yield in the 1-jet 1-tag region. For the other regions included in the fit, the expected fraction of signal events is smaller, 9% in the 2-jet 1-tag region and 3% in the 2-jet 2-tag region, which is the most enriched in $t\bar{t}$. The other backgrounds are small in the 1-jet 1-tag and 2-jet regions where they account for 2% of the total event yield. The 0-tag control regions are enriched in other backgrounds (diboson, $Z +$ jets and non-prompt or fake lepton), which contribute 40–60% of the total event yield.

The $E_T^{\text{miss}}$ distributions of events in the 0-tag regions are shown in figure 2 to demonstrate the good modelling of the other backgrounds. The behaviour of this distribution at low $E_T^{\text{miss}}$ values is a result of the different requirements for same-flavour and opposite-flavour leptons. Figures 3 and 4 show the distributions of kinematic variables of reconstructed objects for the three $b$-tagged regions. The data distributions are well modelled by the background and signal expectations in all regions.

### 5 Analysis

The separation of the $Wt$ signal from the dominant background from top-quark pairs is accomplished through the use of a BDT algorithm [33] in the TMVA framework [73]. The BDTs are trained separately in three regions, 1-jet 1-tag, 2-jet 1-tag and 2-jet 2-tag, using simulated $Wt$ events as signal and simulated $t\bar{t}$ events as background. Three

equal-size $Wt$ samples are combined to reduce sensitivity to the modelling uncertainties and to maximise the number of events available for training: the Powheg-Box+Pythia sample with the DR scheme, the Powheg-Box+Pythia sample with the DS scheme, and the Powheg-Box+Herwig sample with the DR scheme. The AdaBoost boosting algorithm is used [74]. This algorithm increases the event weight for mis-classified events for consecutive trees in the training. The final BDT is then the weighted average over all trees. The list of variables entering the BDT algorithm is chosen based on the power to discriminate the $Wt$ signal from the $t\bar{t}$ background and is derived from a large set of kinematic variables that show good agreement between data and MC simulation. The number of input variables is a compromise between the achievable discrimination power and possible overtraining. As a result of this optimisation procedure, 13, 16, and 16 variables are selected for the 1-jet 1-tag, 2-jet 1-tag, and 2-jet 2-tag regions, respectively.

The BDT input variables used in the three regions are explained below and are listed in table 3 together with their importance ranking. The objects (denoted $o_1, \ldots, o_n$) used to define these kinematic variables are the leading- and second-leading lepton ($\ell_1$ and $\ell_2$) and jet ($j_1$ and $j_2$) as well as $E_T^{\text{miss}}$. The kinematic variables are defined as follows.
\( p_{\text{sys}}^T(o_1 \ldots, o_n) \), magnitude of the vector sum of the transverse momenta of the objects.

- \( \sum E_T \), the scalar sum of transverse energy of calorimeter cells. For cells associated with electrons and jets, the corresponding corrections are applied.

- \( \sigma(p_{\text{sys}}^T(o_1 \ldots, o_n)) \), the ratio of \( p_{\text{sys}}^T \) to \( (H_T + \sum E_T) \), where \( H_T \) is the scalar sum of the transverse momenta of the objects.

- \( \Delta p_T(o_1, o_2) \), the difference in \( p_T \) between the two objects.

- \( \Delta R(o_1, o_2) \), the separation of the two objects in \( \phi-\eta \) space.

- \( m_T(o_1, o_2) \), the transverse mass, given by \( \sqrt{2p_T(o_1)p_T(o_2)(1 - \cos \Delta \phi)} \).

- Centrality\((o_1, o_2)\), the ratio of the scalar sum of the \( p_T \) of the two objects to the sum of their energies.

- \( m(o_1, o_2) \), the invariant mass of the system of the two objects.

- \( m_{T2} \), which contains information about the presence of the two neutrinos from the two \( W \)-boson decays [75–77]. The \( m_{T2} \) algorithm creates candidates for the transverse momenta of the two neutrinos, which must sum to give the missing transverse momentum. These are combined with the momenta of the two leptons to form the transverse mass of two candidate \( W \) bosons, with each also fulfilling a \( W \)-boson mass constraint. For each such candidate pair, the larger of the two transverse masses is kept. Then \( m_{T2} \) is given by the smallest transverse mass in all possible candidate pairs.

- \( E/m(o_1, o_2, o_3) \), the ratio of the energy of the system of the three objects to the invariant mass of this system.

Figure 5 compares the shapes of the most important variables in the 1-jet 1-tag region for \( Wt \) and \( t\bar{t} \) events and shows a comparison of the data and the SM predictions. The most important variable is \( p_{\text{sys}}^T(\ell_1, \ell_2, E_T^{\text{miss}}, j_1) \), which is sensitive to the unidentified \( b \)-quark in \( t\bar{t} \) events. This variable peaks at lower values for \( Wt \) and has a longer tail for \( t\bar{t} \). The second most important variable is the separation of the leading lepton and the jet, in \( \phi-\eta \) space. These two objects originate from the same top quark in \( Wt \) events, leading to a sharper peak than in \( t\bar{t} \) events. Figure 6 shows the most important discriminating variables in the 2-jet regions. Here, the \( p_{\text{sys}}^T \) distribution also peaks at lower values for \( Wt \) than for \( t\bar{t} \), but the distribution is also broader for \( Wt \), resulting in a long tail. The invariant mass variables are important for 2-jet events, where half of the possible lepton-jet pairings correspond to the objects from the decay of one of the top quarks in \( t\bar{t} \) events leading to a peak at lower invariant mass. For \( Wt \), only one quarter of the possible pairings of jets and leptons correspond to the objects from the top-quark decay.

The BDT response for the three regions is shown in figure 7. The \( Wt \) signal is larger at positive BDT response values, while the \( t\bar{t} \) background dominates for negative BDT
Table 3. Discriminating variables used in the training of the BDT for each region. The number indicates the relative importance of this variable, with 1 referring to the most important variable. An empty field means that this variable is not used in this region.
Figure 5. Distributions of the two most important BDT input variables for the 1-jet 1-tag region. The distributions are shown for (a, b) the $p_T$ of the system of the leptons, jet and $E_T^{miss}$ and (c, d) the $\Delta R$ between the leading lepton and the jet. Each contribution is normalised to unit area in (a, c) and to its expectation in (b, d). The hatched area represents the sum in quadrature of the statistical and systematic uncertainties. The last bin includes the overflow.

response values. The BDT range in each region is chosen to ensure sufficient simulation statistics in each bin. The BDT separates the signal from the background in all three regions, although even for high BDT response values in the 1-jet 1-tag region, there remains a large expected background from $t\bar{t}$ events. The BDT responses from figure 7 are used in the profile likelihood fit with this binning.

6 Systematic uncertainties

Systematic uncertainties affect the acceptance estimates for the signal and background processes. Some of the systematic uncertainties also affect the shape of the BDT response. Experimental sources of uncertainty arise from the modelling of jets, leptons and $E_T^{miss}$.

The impact of the uncertainty in the jet energy scale (JES) on the acceptance and shape of the BDT response for $Wt$ and $t\bar{t}$ is evaluated in 22 uncorrelated components, each of which can have a $p_T$ and $\eta$ dependence [44, 78]. The largest components are related
Figure 6. Distributions of the most important BDT input variables in the (a, b) 2-jet 1-tag and (c, d) 2-jet 2-tag regions. The distributions are shown for (a, b) the invariant mass of the system of the leading lepton and the second-leading jet and (c, d) the $p_T$ of the system of the two jets. Each contribution is normalised to unit area in (a, c) and to its expectation in (b, d). The hatched area represents the sum in quadrature of the statistical and systematic uncertainties. The last bin includes the overflow.

to the modelling and the heavy-flavour correction, with an acceptance uncertainty for $Wt$ and $t\bar{t}$ events of 1-2%. The shape uncertainty is taken into account for the JES component with the largest impact on the fit result (JES modelling component 1). The jet energy resolution uncertainty is evaluated by smearing the energy of each jet in the simulation and symmetrising the resulting change in acceptance and BDT response shape [79]. The resulting acceptance uncertainty for $Wt$ and $t\bar{t}$ events is 1-3%, and the shape uncertainty is taken into account.

The uncertainties in the modelling of the jet reconstruction and the jet vertex fraction requirement are evaluated by randomly discarding jets according to the difference in jet reconstruction efficiency between the data and MC simulation and by varying the the jet vertex fraction requirement, respectively. These uncertainties have an impact on the acceptance for $Wt$ and $t\bar{t}$ events of less than 1%. They do not change the shape of the BDT response.

Further uncertainties arise from the modelling of the trigger, reconstruction, and identification efficiencies for electrons [80] and muons [40], as well as from the modelling of
Figure 7. BDT response for (a, b) 1-jet 1-tag, (c, d) 2-jet 1-tag and (e, f) 2-jet 2-tag events. Each contribution is normalised to unit area in (a, c, e) and to its expectation in (b, d, f). The hatched area represents the sum in quadrature of the statistical and systematic uncertainties. The first bin includes the underflow and the last bin the overflow.

the electron and muon energy scale and resolution [40, 81]. These have an effect on the acceptance for $Wt$ and $tt$ events of less than 1%, except for the electron identification uncertainty, which has an acceptance uncertainty for $Wt$ and $tt$ of 2%. These uncertainties do not change the shape of the BDT response.
Uncertainties in the modelling of the $b$-tagging efficiency and mis-tag rates are estimated from data [47, 48]. These uncertainties depend on the jet flavour and $p_T$, and for mis-tag rates also on jet $\eta$. The uncertainty for $b$-jets is evaluated in six components, with the largest component having an acceptance uncertainty for $Wt$ and $t\bar{t}$ events of 1–4%, depending on the analysis region [48]. The $b$-tag modelling uncertainties do not change the shape of the BDT response.

The variations in lepton and jet energies are propagated to the $E_T^{\text{miss}}$ value. This uncertainty has additional contributions from the modelling of the energy deposits which are not associated with any reconstructed object [49]. Both an energy scale and an energy resolution component are considered. The corresponding acceptance uncertainty for $Wt$ and $t\bar{t}$ events is less than 0.3%. The $E_T^{\text{miss}}$ scale component also alters the shape of the BDT response.

Theoretical uncertainties are evaluated for the signal as well as the $t\bar{t}$ predictions. Figure 8 shows the relative shift of the BDT response associated with four of the theory modelling uncertainties. The uncertainty on the $Wt$ signal and the $t\bar{t}$ background associated with initial- and final-state radiation (ISR/FSR) is evaluated using POWHEG-BOX interfaced to PYTHIA. The renormalisation scale associated with the strong coupling $\alpha_s$ is varied up and down by a factor of two in the matrix-element calculation and a PYTHIA Perugia 2012 tune is used to create samples with increased and decreased levels of radiation that are compatible with 7 TeV ATLAS data [82]. For $t\bar{t}$, the $\text{hdamp}$ parameter of POWHEG-BOX [51], which affects the amount of QCD radiation, is varied together with ISR/FSR. This uncertainty is treated as uncorrelated between $Wt$ and $t\bar{t}$ events. Figure 8 shows that this uncertainty has a large effect on the acceptance and also alters the shape of the BDT response.

The uncertainty associated with the NLO matching method is evaluated by comparing POWHEG-BOX with MC@NLO, both interfaced to HERWIG. Figure 8 shows that this uncertainty has a dependence on the shape of the BDT response. For $Wt$ production, the largest impact of this uncertainty is to shift events between the 1-jet 1-tag and 2-jet 2-tag regions. For $t\bar{t}$ events, the impact of this uncertainty is on the acceptance, where it is 11–12%. This uncertainty is treated as correlated between $Wt$ and $t\bar{t}$ events.

The uncertainty associated with the modelling of the hadronisation and parton shower is evaluated by comparing samples where POWHEG-BOX is interfaced with PYTHIA to those where it is interfaced with HERWIG. This uncertainty alters the shape of the BDT response.

For the $Wt$ signal, the uncertainty associated with the scheme used to remove overlap with $t\bar{t}$ is evaluated by comparing the two different schemes: the nominal sample, generated with the DR scheme, is compared to a sample generated with the DS scheme. The relative shift of the BDT response is shown in figure 8. The relative shift of this uncertainty is about 5% in the signal region for 1-jet 1-tag events, and grows to large values in the background-dominated region for 2-jet events, where its evaluation is limited by simulation statistics and the predicted event yield is very small. This uncertainty alters the shape of the BDT response.

The evaluation of the PDF uncertainty follows the PDF4LHC prescription [31] using three different PDF sets (CT10, MSTW2008NLO68CL [28] and NNPDF2.3 [32]).
uncertainty on the acceptance for $Wt$ and $t\bar{t}$ events is evaluated in each of the three analysis regions. The PDF uncertainty is considered correlated between $Wt$ and $t\bar{t}$ events, except for $t\bar{t}$ 1-jet events, for which it is considered to be uncorrelated. The PDF uncertainty components that affect the $t\bar{t}$ acceptance in this region differ from the uncertainty components that affect the $t\bar{t}$ acceptance in the other regions [83].

The normalisation of the $t\bar{t}$ background has an uncertainty of 6% [65, 66]. The diboson background process has an uncertainty of 30% for 1-jet events and 40% for 2-jet events [84], which is treated as uncorrelated between different regions. The $Z$+jets and non-prompt or fake-lepton backgrounds have normalisation uncertainties of 60% to account for possible mismodelling of the jet multiplicity and the acceptance of these small backgrounds [85, 86]. The $Z$+jets and non-prompt or fake-lepton normalisation uncertainties are treated as uncorrelated between background sources and regions.

The uncertainty on the integrated luminosity is 2.8%. It is derived, following the same methodology as that detailed in ref. [87], from a preliminary calibration of the luminosity scale derived from beam-separation scans performed in November 2012. The luminosity uncertainty enters in the extraction of the cross-section as well as in the normalisation

---

**Figure 8.** Relative shift of the BDT response associated with systematic variations of ISR/FSR, NLO matching method, DR/DS and hadronisation for (a) 1-jet 1-tag, (b) 2-jet 1-tag, and (c) 2-jet 2-tag events. DR refers to the diagram-removal scheme, DS to the diagram-subtraction scheme.
of the background processes that are normalised to theory predictions. The statistical uncertainty due to the finite size of the simulation samples is also taken into account.

7 Results

7.1 Measurement of the inclusive cross-section

A profile likelihood fit to the BDT classifier distributions is performed, using the RooStats software [88, 89], in order to determine the inclusive $Wt$ cross-section, utilising the 1-jet 1-tag, 2-jet 1-tag, and 2-jet 2-tag regions. The inclusion of the 2-jet regions provides additional signal sensitivity and also helps to constrain the $t\bar{t}$ background normalisation and systematic uncertainties.

The binned likelihood function is constructed as the product of Poisson probability terms over all bins considered in the analysis. This likelihood depends on the signal-strength parameter $\mu$, which is a multiplicative factor on the unconstrained $Wt$ yield prediction. Nuisance parameters (denoted $\theta$) are used to encode the effects of the various sources of systematic uncertainty on the signal and background expectations. These nuisance parameters are implemented in the likelihood function with multiplicative Gaussian or log-normal constraints with mean $\theta_0$ and standard deviation $\Delta\theta$. The likelihood is then maximised with respect to the full set of $\mu$ and $\theta$ parameters. The values of these parameters after maximisation are referred to as $\mu^\text{obs}$, $\theta^\text{obs}$, and $\Delta\theta^\text{obs}$.

The expected cross-section is obtained from a fit to the so-called Asimov dataset [90], with the signal and all backgrounds scaled to their predicted sizes [26]. The expected measurement is $\mu^\text{exp} = 1.00^{+0.17}_{-0.18}$. The observed result for the signal strength is $\mu^\text{obs} = 1.03^{+0.16}_{-0.17}$, which corresponds to a measured cross-section of $23.0 \pm 1.3 \text{(stat.)}^{+3.2}_{-3.3} \text{(syst.)} \pm 1.1 \text{(lumi.)} \text{pb}$. Including systematic uncertainties, the observed (expected) significance of the signal compared to the background-only hypothesis is 7.7 (6.9) standard deviations, obtained using an asymptotic approximation [90].

The post-fit (pre-fit) effect of each individual systematic uncertainty on $\mu$ is calculated by fixing the corresponding nuisance parameter at $\theta + \Delta\theta$ and performing the fit again. The difference between the default and the modified $\mu$, $\Delta\mu$, represents the effect on $\mu$ of this particular uncertainty. The pull ($(\hat{\theta} - \theta_0)/\Delta\theta$), and the pre-fit and post-fit impacts for the nuisance parameters with the largest impact on $\mu$ are shown in figure 9. Since the total number of observed events in the 2-jet regions is about 14000, with a $Wt$ signal fraction of about 6%, the nuisance parameters that have a $t\bar{t}$ acceptance uncertainty of more than about 2% can be constrained in the fit. This applies to the jet energy resolution and $t\bar{t}$ normalisation uncertainties, amongst others. The $E_T^{\text{miss}}$ scale uncertainty has a shape dependence in the 1-jet 1-tag region for $Wt$ and $t\bar{t}$, which results in the corresponding nuisance parameter being shifted but not much constrained. The theory modelling uncertainties due to ISR/FSR, DR/DS, and NLO matching method have large pre-fit and post-fit impacts. The nuisance parameter for ISR/FSR $Wt$ is shifted and constrained in the fit due to its BDT response shape dependence, shown in figure 8. This uncertainty has the largest impact on $\mu$, both pre-fit and post-fit. The ISR/FSR $t\bar{t}$ uncertainty has a smaller post-fit impact on $\mu$ and is constrained due its acceptance and
shape dependence. In a test where the ISR/FSR uncertainty is considered to be correlated between $Wt$ and $t\bar{t}$ events, the expected uncertainty on $\mu$ is reduced to $0.16$. The nuisance parameter for the NLO matching method uncertainty is constrained by the $t\bar{t}$ background because of the large acceptance component and shape dependence of the NLO matching method uncertainty.

Table 4 summarises the contributions from the various sources of systematic uncertainty to the uncertainties on the observed fit result. The total uncertainty in the table is the uncertainty obtained from the full fit, and is therefore not identical to the sum in quadrature of the components, due to correlations that the fit induces between the uncer-
Table 4. Summary of the relative uncertainties on the $Wt$ cross-section measurement. Detector uncertainties are grouped into categories. All sources of uncertainty within a category are added in quadrature to obtain the category uncertainty.

7.2 Constraints on $|f_{LV}V_{tb}|$ and $|V_{tb}|$

The inclusive cross-section measurement provides a direct determination of the magnitude of the CKM matrix element $V_{tb}$. The ratio of the measured cross-section to the theoretical prediction is equal to $|f_{LV}V_{tb}|^2$, where the form factor $f_{LV}$ could be modified by new physics or radiative corrections through anomalous coupling contributions, for example those in refs. [3, 91, 92]. The $Wt$ production and top-quark decays through $|V_{ts}|$ and $|V_{td}|$ are assumed to be small. A lower limit on $|V_{tb}|$ is obtained for $f_{LV} = 1$ as in the SM, without assuming CKM unitarity [5, 93]. An additional systematic uncertainty due to a variation of the top-quark mass by 1 GeV is included in the $V_{tb}$ extraction. The uncertainties on the theoretical cross-section due to the variation of the renormalisation and factorisation scale (0.6 pb), the PDF uncertainty (1.4 pb), and the beam-energy uncertainty [94] (0.38 pb) are also accounted for.

The value for $|f_{LV}V_{tb}|$ is extracted from the $|f_{LV}V_{tb}|^2$ likelihood, which is assumed to be Gaussian. The lower limit on $|V_{tb}|^2$ corresponds to 95% of the integral of this likelihood,
setting $f_{LV} = 1$ and starting at 1. The measured value of $|f_{LV}V_{tb}|$ is $1.01 \pm 0.10$, and the corresponding lower limit on $|V_{tb}|$ at the 95% confidence level is 0.80.

8 Cross-section measurement inside a fiducial acceptance

The cross-section for the production of events containing a top quark and a $W$ boson is measured in a fiducial region to allow a more robust comparison to the theoretical prediction without extrapolating to regions outside of the detector acceptance. The fiducial measurement reduces the sensitivity of the cross-section to theory modelling uncertainties. The measurement can also be compared to particle-level predictions for the inclusive $WWb$ and $WWbb$ processes at NLO, once those calculations become available [36, 95]. The fiducial acceptance requires two leptons and exactly one $b$-jet at the particle level. This encompasses not only $Wt$ production but also $t\bar{t}$ production where one of the $b$-quarks from the top-quark decays is not in the particle-level acceptance. The fiducial cross-section is measured by fitting the sum of the $Wt$ and $t\bar{t}$ contributions to data in the 1-jet 1-tag region. Control regions are not used in the fit.

Table 5. Number of expected events at the particle-level and for the detector-level selection for $Wt$ and $t\bar{t}$. The uncertainty for the particle-level includes ISR/FSR, NLO matching method, and for $Wt$ also hadronisation, all added in quadrature. The uncertainty for the detector-level selection includes all sources of uncertainty, added in quadrature.

8.1 Fiducial selection

The definition of the fiducial acceptance is based on MC simulation and uses particle-level physics objects constructed of stable particles with a mean lifetime $\tau > 0.3 \times 10^{-10}$ s. Electrons and muons are required to originate from $W$-boson decays, either directly or via leptonically decaying $\tau$ leptons. The $p_T$ of each of the leptons is corrected by adding the energy and momentum of photons inside a cone of size $\Delta R = 0.1$ around the lepton direction. Electrons and muons are required to have $p_T > 25$ GeV and $|\eta| < 2.5$. Jets are clustered from particles using the anti-$k_t$ algorithm with radius parameter $R = 0.4$. Neutrinos, electrons and muons from $W$-boson decays as well as particles resulting from pileup are excluded from jet clustering. Particles from the underlying event are included. The particle-level jets are required to have $p_T > 20$ GeV and $|\eta| < 2.5$ and are matched with nearby $b$-hadrons with a $p_T$ of at least 5 GeV using the ghost tagging method [96]. Jets within $\Delta R = 0.2$ of the nearest electron are removed from the list. Following that, electrons and muons within $\Delta R = 0.4$ of the nearest jet are removed. Missing transverse momentum is calculated using neutrinos from $W$-boson decays. The $Wt$ and $t\bar{t}$ events pass the fiducial selection if they have exactly two leptons, exactly one $b$-jet and $E_T^{miss} > 20$ GeV. The numbers of simulated $Wt$ and $t\bar{t}$ events passing this fiducial selection are shown in table 5, and $Wt$ production contributes 26% of these particle-level events.

Simulated $Wt$ and $t\bar{t}$ events that satisfy the detector-level selection criteria are separated into two categories: in-fiducial (satisfying the fiducial selection criteria) and out-of-fiducial (the rest). Table 5 shows the number of events for $Wt$ and $t\bar{t}$ in each category. The $Wt$ contribution is 25% of the in-fiducial events, but only 10% of the out-of-fiducial events. The out-of-fiducial events that pass the detector-level selection typically have two or more particle-level jets, only one of which is also reconstructed at the detector level. Thus the $t\bar{t}$ contribution to the out-of-fiducial events is larger.

8.2 Systematic uncertainties

The sources of systematic uncertainty in the inclusive cross-section measurement are also considered for the fiducial measurement. The object reconstruction and background-normalisation uncertainties also apply in this measurement (except the $t\bar{t}$ normalisation uncertainty, as discussed below). For in-fiducial events, a variation in the theory modelling uncertainties (DR/DS, ISR/FSR, hadronisation, NLO matching method, and PDF) changes the detector-level and fiducial acceptances in the same direction, which reduces the

impact of these uncertainties. Since this does not affect out-of-fiducial events, these theory modelling uncertainties are treated as uncorrelated between in- and out-of-fiducial events.

An additional uncertainty accounts for the relative fractions of $Wt$ and $t\bar{t}$ due to the uncertainty on the theoretical predictions. The fraction of each type of signal is allowed to vary within their theoretical predictions, keeping the sum constant.

### 8.3 Results

The fiducial cross-section is measured in a profile likelihood fit to data in the 1-jet 1-tag region. In-fiducial and out-of-fiducial $Wt$ and $t\bar{t}$ events are scaled by the same cross-section scale factor $\mu_{\text{fid}}$ in the fit. The measured fiducial cross-section for $Wt$ and $t\bar{t}$ production is $0.85 \pm 0.01 \text{ (stat.)}^{+0.06}_{-0.07} \text{ (syst.)} \pm 0.03 \text{ (lumi.)} \text{ pb}$, which corresponds to a total uncertainty of 8%. The expected uncertainty is also 8%. The impact of the systematic uncertainties on this measurement is summarised in table 6. The relative uncertainties are smaller in the fiducial measurement than in the inclusive measurement (cf. table 4) because both $Wt$ and $t\bar{t}$ events are considered signal and because of the definition of the fiducial acceptance. The only exception is the $b$-tag uncertainty, which is larger in the fiducial measurement because only 1-jet 1-tag events are used in the fit.

The measured fiducial cross-section is compared to theoretical predictions for the sum of the fiducial $Wt$ and $t\bar{t}$ cross-sections in figure 11. The uncertainty on the theory predictions accounts for scale and PDF contributions. The MSTW2008 and NNPDF2.3 predictions are obtained by re-weighting the simulated Mc@NLO sample. The uppermost result
for the predicted fiducial cross-section is based on the fiducial acceptances and the sample normalisation utilised in this analysis. The fiducial acceptances are computed from the nominal POWHEG-BOX+PYTHIA samples. The $Wt$ and $tt$ cross-sections are normalised to their NLO+NNLL and NNLO+NNLL predictions, respectively. The other results utilise the theoretical cross-sections as computed by the respective generator.

9 Conclusion

The inclusive cross-section for the production of a single top quark in association with a $W$ boson has been measured in proton-proton collisions at a centre-of-mass energy of 8 TeV, using dilepton events from 20.3 fb$^{-1}$ of data recorded by the ATLAS detector at the LHC. $Wt$ production is observed with a significance of 7.7 $\sigma$. The measured cross-section is

$$23.0 \pm 1.3 \text{(stat.)}^{+3.2}_{-3.5} \text{(syst.)} \pm 1.1 \text{(lumi.)} \text{ pb},$$

for the predicted fiducial cross-section requiring two leptons with $p_T > 25$ GeV and $|\eta| < 2.5$, one jet with $p_T > 20$ GeV and $|\eta| < 2.5$, and $E_T^{\text{miss}} > 20$ GeV. The predictions are computed at NLO accuracy for the fiducial acceptance and the inclusive cross-section, except for the top line, for which the inclusive cross-sections for $Wt$ and $tt$ are computed at NLO+NNLL and NNLO+NNLL accuracy, respectively.
in agreement with the NLO+NNLL expectation. The measured cross-section is used to extract a direct measurement of the left-handed form factor times the CKM matrix element $|f_{LV}V_{tb}|$ of 1.01 ± 0.10. The lower limit on $|V_{tb}|$ is 0.80 at the 95% CL, without assuming unitarity of the CKM matrix. The cross-section for the production of a $W$ boson and a top quark (including $Wt$ and $t\bar{t}$) has also been measured in a fiducial acceptance requiring two leptons with $p_T > 25$ GeV and $|\eta| < 2.5$, one jet with $p_T > 20$ GeV and $|\eta| < 2.5$, and $E_T^{\text{miss}} > 20$ GeV. The fiducial cross-section is

$$0.85 \pm 0.01 \text{ (stat.)} \pm 0.07 \text{ (syst.)} \pm 0.03 \text{ (lumi.)} \text{ pb}.$$ 

Acknowledgments

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTR, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; IN2P3-CNRS, CEA-IRFU, France; GNSF, Georgia; BMBF, HGF, and MPG, Germany; GSRT, Greece; RGC, Hong Kong SAR, China; ISF, I-CORE and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; RCN, Norway; MNiSW and NCN, Poland; FCT, Portugal; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SERI, SNSF and Cantons of Bern and Geneva, Switzerland; MOST, Taiwan; TAEK, Turkey; STFC, United Kingdom; DOE and NSF, United States of America. In addition, individual groups and members have received support from BCKDF, the Canada Council, CANARIE, CRC, Compute Canada, FQRNT, and the Ontario Innovation Trust, Canada; EPLANET, ERC, FP7, Horizon 2020 and Marie Skłodowska-Curie Actions, European Union; Investissements d’Avenir Labex and Idex, ANR, Region Auvergne and Fondation Partager le Savoir, France; DFG and AvH Foundation, Germany; Herakleitos, Thales and Aristeia programmes co-financed by EU-ESF and the Greek NSRF; BSF, GIF and Minerva, Israel; BRF, Norway; the Royal Society and Leverhulme Trust, United Kingdom.

The crucial computing support from all WLCG partners is acknowledged gratefully, in particular from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (U.K.) and BNL (U.S.A.) and in the Tier-2 facilities worldwide.
