ABSTRACT
Epidemiological studies have indicated a relationship between coronary heart disease (CHD) and periodontitis. Recently, CDKN2BAS was reported as a shared genetic risk factor of CHD and aggressive periodontitis (AgP), but the causative variant has remained unknown. To identify and validate risk variants in different European populations, we first explored 150 kb of the genetic region of CDKN2BAS including the adjacent genes CDKN2A and CDKN2B, covering 51 tagging single nucleotide polymorphisms (tagSNPs) in AgP and chronic periodontitis (CP) in individuals of Dutch origin (n = 313). In a second step, we tested the significant SNP associations in an independent AgP and CP population of German origin (n = 1264). For the tagSNPs rs1360590, rs3217992, and rs518394, we could validate the associations with AgP before and after adjustment for the covariates smoking, gender and diabetes, with SNP rs3217992 being the most significant (OR 1.48, 95% CI 1.19 to 1.85; p = 0.0004). We further showed in vivo gene expression of CDKN2BAS, CDKN2A, CDKN2B, and CDK4 in healthy and inflamed gingival epithelium (GE) and connective tissue (CT), and detected a significantly higher expression of CDKN2BAS in healthy CT compared to GE (p = 0.004). After 24 h of stimulation with Porphyromonas gingivalis in Streptococcus gordonii pre-treated gingival fibroblast (HGF) and cultured gingival epithelial cells (GECs), we observed a 25-fold and fourfold increase of CDKN2BAS gene expression in HGFs (p = 0.003) and GECs (p = 0.004), respectively. Considering the global importance of CDKN2BAS in the disease risk of CHD, this observation supports the theory of inflammatory components in the disease physiology of CHD.

INTRODUCTION
Coronary heart disease (CHD) is the leading cause of death worldwide and is considered to be a complex multifactorial disease. Epidemiological studies have shown a significant correlation between periodontal health and the occurrence of cardiovascular events. Periodontitis and CHD are both strongly promoted by very similar environmental and behavioural risk factors, with smoking and diabetes being the most prominent. Furthermore, the same pathogenic bacterial strains were observed in both inflamed gingival tissue and atherosclerotic plaques. It has also been shown that periodontal treatment results in improvement of endothelial function, a marker for risk prediction of cardiovascular events. Recently, a major genetic susceptibility locus for CHD was identified by various genome wide association studies (GWAS). This locus is located within the chromosomal region 9p21.3, mapping to the large non-coding (nc) antisense RNA transcript CDKN2BAS, formerly called ANRIL. This association was verified by a subsequent meta-analysis and by a large scale replication study, making this genetic region the best replicated CHD associated risk locus to date. In addition, variants within this region were independently found to be associated with type 2 diabetes, abdominal aortic and intracranial aneurysms, ischaemic stroke, Alzheimer’s disease and vascular dementia, and high grade glioma susceptibility. Recently, we demonstrated the association of a highly increased risk for aggressive periodontitis (AgP) with specific variants of CDKN2BAS. However, despite extensive fine mapping and functional studies, the causative variant and the functional role of CDKN2BAS has remained unknown.

In the present study, we aimed to identify genetic risk variants of CDKN2BAS that are shared by different European case–control populations of aggressive and chronic periodontitis. To this end, we covered >150 kb with 51 tagging single nucleotide polymorphisms (tagSNPs) mapping to CDKN2BAS and the adjacent cell cycle inhibitor genes CDKN2A and CDKN2B. We explored the SNP associations in two populations of AgP and chronic periodontitis (CP) of Dutch origin (n = 313), and replicated the significant associations in two populations of AgP and CP of German origin (n = 1264).
muscle cells, fibroblasts, and macrophages, has been demonstrated.\textsuperscript{30} \textsuperscript{32} \textsuperscript{33} To study the tissue specific expression in the gingiva, we quantified the mRNA transcription pattern of CDKN2BAS, CDKN2A and CDKN2B in healthy and inflamed human gingival tissue samples. Additionally, we studied the gingival expression of CDK4, a cell cycle regulating kinase that is directly inhibited by CDKN2A and CDKN2B. To explore the possibility that both periodontitis and CHD share an inflammatory pathophysiology, we assessed the potential role of pathogenic bacteria in the transcriptional regulation of these genes in different gingival tissues.

**PATIENTS AND METHODS**

**Study population**

The patient and control samples of the CP and AgP association studies were recruited across Germany and the Netherlands as previously described.\textsuperscript{34} Only individuals of German and Dutch ethnicity were included, judged upon the location of both parental birthplaces. Before the study, the genetic sub-structure of the German and Dutch populations had been assessed,\textsuperscript{35} \textsuperscript{36} indicating only negligible sub-structures and therefore allowing an analysis of the German and Dutch individuals in a single genetic study without the risk of substantial population stratification. A detailed description of the study population is given in table 1 and in the supplementary information. Informed written consent was obtained from all subjects recruited into this study. The study was approved by each institute’s own ethical review board (Medical Ethical Committee, Universities of Bonn, Dresden, Kiel and Munich, and Medical Ethical Committee, Academic Medical Center, University of Amsterdam, The Netherlands).

**DNA extraction and genotyping**

Genomic DNA was extracted from blood (Invisorb Blood Universal Kit, Invitex, Berlin, Germany) or mouthwash samples,\textsuperscript{37} and was amplified by whole genome amplification (GenomiPhi, Amersham, Uppsala, Sweden). TagSNPs were selected from the CEU data of the International HapMap project (http://www.hapmap.org, NCBI build 36, 2008-03) using the Tagger feature\textsuperscript{38} of Haploview 4.0.\textsuperscript{39} TagSNPs were defined by pair-wise linkage disequilibrium tagging ($r^2 > 0.8$). Genotyping was carried out using the SNPlex and TaqMan Genotyping System (Applied Biosystems, Foster City, California, USA) on an automated platform, using TECAN Freedom EVO and 96-well and 384-well TEMO liquid handling robots (TECAN, Ménne- dorf, Switzerland). Genotypes were generated by automatic calling using the Genemapper 4.0 software (Applied Biosystems) with the following settings: $\xi$ separation >6, angle separation for two cluster SNPs <1.2 rad, median cluster intensity >2.2 logs. Genotypes were further reviewed manually and call rates $\geq$90% in each sample set were required.

**Gingival tissue samples and cell culture**

For gene expression study, gingival tissue samples were obtained from individuals with healthy gingival conditions and no periodontitis (n=10) as well as from patients with advanced CP (n=10). All biopsies were collected from healthy patients (age 19–58 years) who underwent third-molar extraction or periodontal surgery and from patients with advanced CP. Healthy gingival conditions were defined as follows: no redness, no swelling, no bleeding on probing, and with periodontal pockets $\leq$3 mm. Patients with advanced CP showed all typical clinical signs of periodontal in- flammation (redness, swelling, bleeding on probing) and a periodontal probing depth $\geq$6 mm. For culture of gingival epithelial cells (GECs) (n=5) and human gingival fibroblasts (HGFs) (n=5), gingival epithelial tissue samples were prepared as previously described.\textsuperscript{40} Epithelial cells were cultured in keratinocyte growth medium (KGM) using supplements provided with the medium (PAA, Cölbe, Germany) and 1% antibiotics (penicillin, streptomycin, amphotericin; PAA), whereas fibroblasts were cultured using Dulbecco’s modified Eagle’s medium (DMEM; PAA) supplemented with 1% antibiotics (penicillin, streptomycin, amphotericin; PAA) and 10% fetal bovine serum (FBS; PAA). Both GECs and HGFs were cultured at 37°C in a humidified atmosphere (5% carbon dioxide).

**Bacterial cell culture and stimulation experiments**

Wild-type Porphyromonas gingivalis strain ATCC 35277 was cultured under anaerobic conditions, whereas Streptococcus gordontii was grown under aerobic conditions as previously described.\textsuperscript{41} \textsuperscript{42} Bacterial numbers were determined by absorbance measurement using a spectrophotometer (Biochrom AG, Berlin, Germany). To mimic early stages of inflammation and to test

the potential transcriptional response of these genes, the commensal oral bacterium *S gordonii* and the pathogenic oral bacterium *P gingivalis*, commonly present during severe periodontal infection, were chosen to create an in vitro model to mimic periodontal infection of GECs and HGFs. For stimulation experiments, GECs and HGFs were grown to 80% confluence and then incubated with *P gingivalis* and *S gordonii*, respectively, using an amount equivalent to a multiplicity of infection of 100:1, for either 6 h or 24 h. Experimental groups were: (1) unstimulated GECs and HGFs, (2) control cells (GECs and HGFs) treated with blank bacterial medium for *S gordonii* not containing bacterial cells; (3) control cells (GECs and HGFs) treated with blank bacterial medium for *P gingivalis* not containing bacterial cells; (4) stimulation of GECs and HGFs with *S gordonii*; (5) stimulation of GECs and HGFs with *P gingivalis*; and (6) pre-incubation of GECs and HGFs with *S gordonii* followed by medium change and stimulation with *P gingivalis*. Each stimulation experiment was performed in triplicate, using cells from three different donors.

**RNA extraction and PCR conditions**

To extract mRNA from the epithelial and the connective tissue layer separately, biopsies were enzymatically dissected using 5 ml dispase (Cascade Biologics, Paisley, UK) for 6 h on ice. After separation of gingival biopsies, total RNA was extracted from both epithelium and connective tissue (CT) using the RNeasy Protection Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer’s instructions.

Subsequent to in vitro stimulation experiments on GECs and HGFs, total RNA was extracted as described above. The reverse transcription reaction with 500 ng of total RNA was performed using iScript (Bio-Rad, Munich, Germany) following the manufacturer’s instructions.

Quantitative analysis of the cDNA was performed using the iCycler (Bio-Rad) and the QuantiFast SYBR Green PCR kit (Qiagen) according to the manufacturer’s instructions. PCR reactions were carried out in 96-well plates in a total volume of 25 μl, including 10 ng of cDNA and 250 nM primers. At the end of each real-time PCR, melting curve analysis was performed to confirm that the amplified product was specific. Gene expression levels in the gingival epithelium and the gingival connective tissue were analysed by normalisation to the gene expression levels in healthy gingival epithelium. All sample values were normalised to the expression of the housekeeping gene glyceraldehyde-3-dehydrogenase (GAPDH, GeneGlobe primer, Qiagen) and relative gene expression was calculated using the delta-delta Ct (threshold cycle) method. PCR controls were performed using water. Primer sequences are given in supplementary table 1.

**Statistical analysis**

Markers were checked for deviation from Hardy–Weinberg equilibrium (HWE) in controls to a significance level of α=0.05 before inclusion into the analysis. We assessed the significance of phenotypic association with single marker alleles and genotypes using χ² and Fisher’s exact tests for 2×2 and 2×3 contingency tables, respectively. Logistic regression analysis allowing for covariate adjustment was performed in the R statistical environment, version 2.8.1. Significance was assessed by a likelihood ratio test. Values of p≤0.05 were considered nominally significant. Akaike’s information criterion (AIC) was used to choose the model that best explained the underlying associations. Linkage disequilibrium (LD) measures were calculated and plotted using Haploview. Quantitative real time (qRT-PCR) data were analysed using the Mann–Whitney Test (SPSS, Version 18, Munich, Germany). The significance level was set at p≤0.05.

**RESULTS**

**Association study with aggressive periodontitis**

To analyse potential genetic associations within the entire CDKN2BAS region, we selected 51 tagSNPs covering 150 kb. These SNPs were genotyped in our combined population of 159 Dutch generalised and localised AgP patients and 421 Dutch healthy controls. In our previous study on the association of CDKN2BAS with AgP, we demonstrated that the allele frequencies at this genetic locus were very similar between localised and generalised AgP cases, allowing the pooling of both sub-phenotypes to increase the statistical power for detecting associated variants. In a second step, we validated the significant SNPs in an independent panel of our 501 German patients with generalised or localised AgP and 963 German controls. In a third step, we subsequently tested the selected tagSNPs in this genetic region for potential associations with chronic periodontitis in a panel of 154 Dutch CF cases, and replicated the significant associations in an independent panel of 740 German CF cases. To increase the statistical power, we used the same panels of Dutch and German controls for the association tests performed with the Dutch and German AgP and CF patients, respectively (table 1).

Out of the 51 tagSNPs, eight were found to have a minor allele frequency (MAF) below 0.01 in the Dutch populations. These were excluded from the analysis due to their limited expected statistical power. Five further SNPs were excluded due to deviations from HWE in the Dutch controls (p<0.05). One SNP, rs564598, had poor genotyping quality (call rate <0.9) and was excluded from further analyses. In the explorative association study of the Dutch AgP case–control population, four SNPs were nominally significantly associated with AgP before adjustment for the common risk factors of gender, smoking, and diabetes (supplementary table 2). Upon covariate adjustment, seven SNPs were nominally significantly associated (table 2, for genotype and allele frequencies see table 3), with SNP rs3217992 being the most significant (OR 2.53, 95% CI 1.29 to 5.13; p=0.007). Two SNPs, rs1360590 and rs11790231, showed significant associations before and after covariate adjustment (supplementary tables 2 and 3).

These seven nominally significantly associated SNPs were then tested for their association in the German AgP population. One SNP, rs10965224, showed significant deviations from HWE in the German controls (p<0.05) and was excluded from further analyses. Before the covariate adjustment, three of the associations remained significant (rs2177992, rs18394, rs1360590), with SNP rs1560590 being most significantly associated with p=0.0005 (multiplicative genetic model) and an OR of 1.41 (CI 1.16 to 1.72) (supplementary table 4). Upon covariate adjustment, these three SNPs remained significantly associated, with rs3217992 being most significant with p=0.0004 (table 2, supplementary table 5) and an OR of 1.48 (95% CI 1.19 to 1.85). After Bonferroni correction for multiple testing, these three SNPs span a chromosomal region of 38 kb (NCBI build 36.3) and are located within (rs2177992) or downstream of CDKN2B, but were only in moderate LD to each other in our control population (figure 1). Interestingly, none of the SNPs which tagged the large LD region at the 5’ end of CDKN2BAS, and which was most significantly associated with CHD 9 19,20 as well as with AgP...
in our German cases,\textsuperscript{29} was significantly associated with the Dutch AgP patients in this study. The lead SNPs of this region were associated with CHD and the German AgP cases with the lowest AIC value each. Values are given upon adjustment for the covariates smoking, diabetes, and gender for the aggressive periodontitis (AgP) analyses and additionally for age for the chronic periodontitis (CP) analyses, in a logistic regression model.

### Association study with chronic periodontitis

In the next step, we tested the 37 tagSNPs that had passed the pre-assigned QC for their association with the phenotype chronic periodontitis in the explorative Dutch CP population. Five SNPs were significant before covariate adjustment for gender, age, smoking, and diabetes, with SNP rs10965238 being the most significant (OR 0.57, 95% CI 0.38 to 0.84; p=0.004) (supplementary table 7). Upon adjustment, four SNPs remained significant (rs1360590, rs10965224, rs10965238, rs10811658), two of which showed stable associations before and upon covariate adjustment (rs10965238, rs10811658) (figure 1, table 2 and supplementary table 8).

We next tested these three SNPs for their association in the German CP population, again excluding SNP rs10965224 due to its significant deviations from HWE in this control population. Before covariate adjustment, SNP rs10811658 was significantly associated with CP (supplementary table 9). Upon adjustment, this association remained significant in a similar fashion with p=0.025 (OR 0.66, 95% CI 0.46 to 0.95) (table 2). However, Bonferroni correction for multiple testing, this association missed significance at the corrected significant threshold of p<0.0167 for three independent tests. None of the other SNPs tested in this case—control population showed significant associations upon covariate adjustment (supplementary table 10).

**CDKN2BAS, CDKN2A, CDKN2B, and CDK4 mRNA expression in healthy and inflamed gingival tissues**

To show in vivo gene expression of CDKN2BAS, CDKN2A, CDKN2B, and CDK4, the specific mRNA levels of these genes within the epithelium (EPI) and the connective tissue (CT) of gingival biopsies were analysed. We observed tissue specific expression of all four genes in both EPI and CT. In this explorative study, the expression of CDKN2BAS was significantly higher in healthy CT compared to healthy EPI (p=0.004, figure 2A), and this difference remained significant after Bonferroni correction for multiple comparisons. Whereas for CDKN2A no difference in transcript levels was observed between CT and EPI (figure 2B), higher mRNA levels, although not significant in our experiments, were observed for CDKN2B in healthy CT compared to healthy EPI (p=0.019, figure 2C). A trend towards a lower gene expression for CDK4, inhibited by CDKN2A and 2B in vivo, was noticed in CT compared to EPI (figure 2D).

### CDKN2BAS gene expression upregulated in S gordonii pre-treated and P gingivalis stimulated GECs

We next tested whether the genes were differentially regulated in cultured primary gingival epithelial cells (GECs) when exposed to commensal and/or pathogenic periodontal bacteria. We observed a significant increase of the CDKN2BAS gene expression after 24 h of stimulation with pathogenic *P gingivalis*.

transcript levels after 24 h incubation with \(P\) gingivalis in \(S\) gordonii pre-treated GECs (figure 3C). \(CDK4\) expression was significantly reduced after 24 h of stimulation with pathogenic \(P\) gingivalis in commensal \(S\) gordonii pre-treated GECs compared to unstimulated GECs (\(p=0.004\), figure 3D). A similar reduction, not significant in our experiments, was observed between 6 h and 24 h \(P\) gingivalis stimulation after \(S\) gordonii pre-treatment.

**DISCUSSION**

The aim of this study was to identify genetic risk alleles within the genetic region of \(CDKN2BAS\), \(CDKN2A\), \(CDKN2B\) and \(CDK4\) in healthy and inflamed gingival epithelium and connective tissue. (A) \(CDKN2BAS\) transcript levels were higher in healthy connective tissue compared to healthy gingival epithelium (\(p=0.004\)). (B–D) \(CDKN2A\), \(CDKN2B\), and \(CDK4\) mRNA showed no statistically significant differences in transcript levels between healthy or inflamed epithelial and connective gingival tissues. Each box plot represents results derived from 10 different subjects. CT, connective tissue; EPI, gingival epithelial tissue; H, healthy; I, inflamed.

**Figure 2** mRNA levels of \(CDKN2BAS\), \(CDKN2A\), \(CDKN2B\) and \(CDK4\) in healthy and inflamed gingival epithelium and connective tissue. (A) \(CDKN2BAS\) transcript levels were higher in healthy connective tissue compared to healthy gingival epithelium (\(p=0.004\)). (B–D) \(CDKN2A\), \(CDKN2B\), and \(CDK4\) mRNA showed no statistically significant differences in transcript levels between healthy or inflamed epithelial and connective gingival tissues. Each box plot represents results derived from 10 different subjects. CT, connective tissue; EPI, gingival epithelial tissue; H, healthy; I, inflamed.
The risk of periodontitis related to this locus may vary among different ethnic groups, which is suggested by frequency variations of the disease associated rs1353048C allele from 21% in Yoruba to 51% in European and Japanese in HapMap. To identify the true causative variant(s), that may also be different between various ethnic groups, further genetic exploration of this genetic region in much larger analysis populations, including large analysis populations of various ethnic backgrounds, is necessary. A technical limitation of our study was the failure to genotype 16 of the selected tagSNPs in all populations, especially when the moderate LD across most of the genetic region of CDKN2BAS is considered. Here, an LD region harbouring the potential true variant(s) might have been missed. Future studies that will apply deep resequencing of cases carrying the associated variants across CDKN2BAS will obtain the full spectrum of variation in this region, and will be able to identify the causal variant(s) that affect the genetic risk.

In the second part of our study, we analysed the expression patterns of CDKN2BAS, CDKN2A, CDKN2B, and CDK4 in healthy and inflamed gingiva, and assessed if these genes were regulated by a signal transduction cascade sensitive to bacterial infection. All analysed genes were expressed in the gingiva, with CDKN2BAS and CDKN2B both showing the highest mRNA levels of the analysed genes in CT. We did not observe different transcript levels between healthy or inflamed gingival tissues. This could indicate that these genes are not regulated by the...
inflammatory status of the gingiva. However, although healthy gingival samples were taken from areas with no clinical signs of inflammation, surfaces of the oral cavity are constantly exposed to both commensal and pathogenic microorganisms. Therefore, it can be speculated that the clinically healthy gingiva is subjected to challenges similar to those of the early stages of infection. Likewise, gingival samples with periodontitis represent a tissue where constant infection and chronic inflammation occurred over years, and short term responses on the transcriptional level are most likely missed in inflamed gingival tissue samples. Here, an experimental setting that precisely controls for pathogenic infection might be a better way to assess specific transcriptional responses.

Because the functional variant(s) are as yet unknown for both periodontitis as well as for CHD, we did not aim to study the putative biological effects of the associated variants. Thus, we did not distinguish between the allelic background in our cell cultures, but studied the transcription pattern of the selected genes in response to bacterial infection. We observed that after 24 h of stimulation of healthy HGFs and GECs with the pathogenic bacterium \textit{P. gingivalis}, \textit{CDKN2BAS} was significantly upregulated compared to the unstimulated controls. This real-time response of \textit{CDKN2BAS} gene activity to a specific pathogenic inflammatory trigger indicates that \textit{CDKN2BAS} is subjected to pathogen sensitive transcriptional regulation. Furthermore, the clear response after 24 h of stimulation, but the absence of elevated transcript levels after 6 h of stimulation, suggests that \textit{CDKN2BAS} may be located at a downstream position of a putative pathogen sensitive signalling cascade. We further observed a minor but significant downregulation of \textit{CDKN2A} after 24 h of bacterial stimulation in both gingival epithelial tissue and gingival fibroblasts. These large quantitative differences in \textit{CDKN2BAS} and \textit{CDKN2A} transcript levels in response to 24 h bacterial stimulation possibly indicate that \textit{CDKN2A}, unlike \textit{CDKN2BAS}, is not directly regulated by bacterial infection on the transcriptional level, but at a later stage of this signal transduction cascade.

Our observations were in accordance with a very recent study on \textit{CDKN2BAS} function which showed that \textit{CDKN2BAS} transcripts negatively regulate \textit{CDKN2A} expression.\textsuperscript{31} This recent study detected that \textit{CDKN2BAS} transcript initiates in prostate cancer tissues at a start site several hundred bases upstream of the previously reported start site. An antisense construct designed to target this newly identified transcript caused a pronounced increase in the expression of \textit{CDKN2A}, but had a much less profound effect on \textit{CDKN2B}.\textsuperscript{31} In conjunction with various other experiments, the authors concluded that the transcript encoded upstream of the previously reported start site of \textit{CDKN2BAS} controls \textit{CDKN2A} silencing by cis recruitment of polycomb group complex proteins, and in addition functions as an architectural matrix to retain these proteins at the target site. Interestingly, a recent study, which performed genome wide expression profiling

Figure 4  mRNA levels of \textit{CDKN2BAS}, \textit{CDKN2A}, \textit{CDKN2B} and \textit{CDK4} in human gingival fibroblasts after stimulation with \textit{Streptococcus gordonii} and \textit{Porphyromonas gingivalis}. (A) \textit{CDKN2BAS} mRNA levels were significantly increased in non-\textit{S. gordonii} pre-treated (\textit{p}=0.004) and \textit{S. gordonii} pre-treated human gingival fibroblasts (HGFs) (\textit{p}=0.003) after 24 h of stimulation with \textit{P. gingivalis}. (B) \textit{CDKN2A} mRNA levels were significantly reduced in \textit{S. gordonii} pre-treated and 24 h \textit{P. gingivalis} stimulated HGFs compared to unstimulated HGFs (\textit{p}<0.001). (C, D) No significant differences of mRNA levels were observed for \textit{CDKN2B} and \textit{CDK4} mRNA levels in either condition. Each box plot represents values derived from nine independent experiments and cells from three different donors were tested. C, unstimulated cells; HGF, human gingival fibroblasts; MPG, blank medium for \textit{P. gingivalis}; MSG, blank medium for \textit{S. gordonii}; PG, \textit{P. gingivalis}; SG, \textit{S. gordonii}; SG-PG, pre-treatment with \textit{S. gordonii} for 1 h followed by \textit{P. gingivalis} stimulation for 6 h and 24 h.
in healthy individuals who were homozygous for the common and the rare allele of rs1535049, showed that the nature of the genes and pathways linked to \(CDKN2BAS\) transcript levels comprised genes which control cellular proliferation.\textsuperscript{30} These studies did not functionally analyse exons 1–19, but a second antisense construct designed to target exon 3 silenced \(CDKN2A\) to a much lesser extent than the antisense construct upstream of exon 1.\textsuperscript{31} Although the function of this transcript was not studied in detail, it indicates that different \(CDKN2BAS\) transcripts may have different functions. Currently, 10 alternative spliced variants were reported in different tissues as diverse as lung, brain, heart, vascular epithelial tissues, testis, and blood.\textsuperscript{30, 45–46} They may have specific functions in their tissue specific context, additional or alternative to the observed negative control of \(CDKN2A\). Two studies measured the expression of \(CDKN2BAS\) spliced transcript \(NR\_003529\), spanning exons 17 to 18, and found slightly decreased expression which was associated with the risk allele in healthy individuals.\textsuperscript{30, 32}

A study on individuals with clinically suspected CHD revealed that \(NR\_003529\) expression was significantly increased in individuals with atherosclerotic plaque burden, and correlated \(ANRIL\) transcript levels with severity of atherosclerosis.\textsuperscript{32} Our primers for the quantification of \(CDKN2BAS\) transcript levels were designed to detect \(NR\_003529\) transcripts, and we found \(NR\_003529\) upregulation by bacterial infection. The correlation of \(CDKN2BAS\) expression with bacterial infection and increased \(CDKN2BAS\) expression in individuals with atherosclerotic plaque burden add to the theory of inflammatory components in the pathophysiology of CHD. Considering the recent finding on the ability of the 5’ transcript of \(CDKN2BAS\) to recruit and retain regulatory proteins, the functions of the proximal and considerably long sequences of \(CDKN2BAS\) might well have a similar mechanistic function, but may also be able to act in trans.

Theories concerning the actual disease mechanism that is mediated by the causative risk variants of \(CDKN2BAS\) remain speculative, as the exact nature of the causative variants and the target proteins or genes await elucidation. They possibly differ from previous studies because of the different context, additional or alternative to the observed negative control of \(CDKN2A\). Speculation, as the exact nature of the causative variants and the target proteins or genes await elucidation.

**Funding** This study was supported by a research grant from the “Research Center for Inflammation Medicine” of the Medical Faculty, Christian-Albrechts-University, University Medical Center Schleswig-Holstein, Campus Kiel, (Arne S Schaefer, Gesa M Richter), by the German Ministry of Education and Research (BMBF) through a National Genome Research Network (NGFN) grant (Michael Nothnagel, 01GS0809), by grants of the German Research Foundation (DFG) (KF2008, TP3: Arne S Schaefer, Gesa M Richter, Sören Jepsen) (TP2: Henrik Dommsch, Markus Reinartz, Sören Jepsen), by the BMBF through the POGEN biobank project (01GR0468), by a grant from BONFOR of the Medical Faculty, University of Bonn (Sören Jepsen), and by a grant from the ARPA Research Foundation (Birte Grössner-Schreiber, Sören Jepsen), Regensburg, Germany.

**Competing interests** None.

**Patient consent** Obtained.

**Ethics approval** This study was conducted with the approval of the Medical Ethical Committee, Universities of Bonn, Dresden, Kiel and Munich, Germany, and Medical Ethical Committee, Academic Medical Center, University of Amsterdam, the Netherlands.

**Provenance and peer review** Not commissioned; externally peer reviewed.
