Abstract

Crohn’s disease (CD) and celiac disease (CeD) are chronic intestinal inflammatory diseases, involving genetic and environmental factors in their pathogenesis. The two diseases can co-occur within families, and studies suggest that CeD patients have a higher risk to develop CD than the general population. These observations suggest that CD and CeD may share common genetic risk loci. Two such shared loci, IL18RAP and PTPN2, have already been identified independently in these two diseases. The aim of our study was to explicitly identify shared risk loci for these diseases by combining results from genome-wide association study (GWAS) datasets of CD and CeD. Specifically, GWAS results from CeD (768 cases, 1,422 controls) and CD (3,230 cases, 4,829 controls) were combined in a meta-analysis. Nine independent regions had nominal association p-value < 1.0 × 10^{-5} in this meta-analysis and showed evidence of association to the individual diseases in the original scans (p-value < 1.0 × 10^{-5} in CeD and < 1.0 × 10^{-3} in CD). These include the two previously reported shared loci, IL18RAP and PTPN2, with p-values of 3.37 × 10^{-5} and 6.39 × 10^{-5}, respectively, in the meta-analysis. The other seven had not been reported as shared loci and thus were tested in additional CeD (3,149 cases and 4,714 controls) and CD (1,835 cases and 1,669 controls) cohorts. Two of these loci, TAGAP and PUS10, showed significant evidence of replication (Bonferroni corrected p-values < 0.0071) in the combined CeD and CD replication cohorts and were firmly established as shared risk loci of genome-wide significance, with overall combined p-values of 1.55 × 10^{-10} and 1.38 × 10^{-11}, respectively. Through a meta-analysis of GWAS data from CD and CeD, we have identified four shared risk loci: PTPN2, IL18RAP, TAGAP, and PUS10. The combined analysis of the two datasets provided the power, lacking in the individual GWAS for single diseases, to detect shared loci with a relatively small effect.

**Introduction**

Crohn’s disease (CD) and celiac disease (CelD) are both chronic intestinal inflammatory diseases. In CD inflammation can occur throughout the gastrointestinal tract but most commonly affects the ileal part of the small intestine. While the causative antigen(s) for this inflammation is unknown, it is thought that the disease arises as a reaction to the normal commensal flora of the bowel in a genetically susceptible individual [1,2]. In CelD inflammation is limited to the small intestine. CelD is caused by a reaction to gluten, a dietary peptide present in wheat, barley and rye [3,4]. In both CelD and CD contact between antigens and antigen-presenting cells (APCs) seems to be facilitated by an initial increase in intestinal permeability [5]. In both diseases the subsequent inflammatory response follows a T helper 1 pattern characterized by tumor necrosis factor beta (TNF-β) and interferon gamma (IFN-γ) production and a T helper 17 response marked by the production of interleukin 17 [5].

Although uncommon, it has been observed that CelD and CD can co-occur within families or even within individual patients; there appears to be a greater prevalence of CD among CelD patients than in the general population, although the relatively low prevalence of CD makes it difficult to establish this effect [6]. It is now well accepted that the risk for CD and CelD is partly determined by genetic factors, and recently many genetic risk factors for CelD and CD have been identified. Two genetic risk loci were previously shown to be shared between CelD and CD: a locus on 18p11 containing the PTPN2 (protein tyrosine phosphatase, non-receptor type 2) gene and a locus on 2q12 containing the IL18RAP (interleukin 18 receptor accessory protein) gene [7–13]. While these observations confirm the existence of shared risk loci for CD and CelD, additional such shared risk loci are likely to exist.

There are two possible approaches for identifying shared risk loci. One approach is to test known risk loci from one disease in patient-control cohorts from the other disease. This approach has already been successfully applied in a cross study between CelD and type 1 diabetes (T1D), where four shared risk loci were identified some of which were previously unknown to be associated to CelD [11]. However, this approach relies on previously identified risk alleles, indicating that there probably are many more unknown common risk loci for T1D and CelD. In addition, some of the shared loci will not have a large enough effect in the individual diseases to have been identified by previous genetic studies. A second approach that tackles this problem is to analyze genetic data from two similar diseases as a single unified disease phenotype against healthy controls. Such an analysis would be expected to dilute disease-specific genetic associations, but increase the power for finding shared genetic risk loci of small effect in the individual diseases. The availability of genome-wide association studies (GWAS) performed in both CelD and CD provides large case-control genotyping datasets that enabled us to perform a cross-disease genome-wide meta-analysis in the aim of identifying novel shared risk loci.

To identify novel shared risk loci between CelD and CD, we performed a meta-analysis of two recently published GWAS: a large meta-analysis of three CD GWAS by the International IBD Genetics Consortium and a CelD GWAS in a British population. To confirm identified risk loci, we used a combination of Italian and Dutch CD cohorts and of British, Italian and Dutch CelD cohorts.

**Results**

**Meta-analysis**

We have performed a meta-analysis of 471,504 SNPs from genome-wide datasets of CD (3230 cases, 4829 controls) and CelD (768 cases, 1422 controls) in order to identify shared risk loci between these 2 diseases.

A quantile-quantile (Q-Q) plot of the association p-values for single-SNP Z scores from the meta-analysis was performed (Figure S1) and shows an excess of significant associations above what would be expected by chance. We observe a low inflation factor of 1.08, which is expected given the inflation observed in each of the original studies: 1.05 for CelD and 1.16 for CD. A Manhattan plot of the current study (Figure S2) highlights many strong association signals, several of which correspond to previously reported CD and CelD loci; however, most of these show strong association in only one of the 2 diseases and have thus not been followed up due to the design of the current study. In addition, given the design of the original CelD GWAS, which included only individuals that were positive for the risk-associated allele HLA-DQ2, association to the major histocompatibility complex (MHC) region in CelD was of no relevance since it was artificially inflated. Therefore the MHC region (Chr6:22700000–35000000 from the NCBI B36 genome build) was removed from our analysis.

The meta-analysis of the CD and CelD datasets identified 25 SNPs, from 10 independent regions, that met our criteria for association (association with CelD at p-value <1×10^{-2} and with CD at p-value <1×10^{-3} in the original scans, as well as a nominal association p-value more significant than 1.0×10^{-3} in the meta-analysis) (Table 1 and Table S2). This is more than expected by chance, as we would expect no more than 3 independent regions to meet our criteria, which encouraged us to explore these specific loci further.

The strongest association signal identified in our scan was to the well accepted CD associated risk locus CARD15 (p-values of 3.42×10^{-32}, 3.77×10^{-3} and 1.30×10^{-21} in the CD, CelD and scan datasets respectively). Given the strength and the width of the association signal peak at this locus in the CD dataset, our chances of detecting a false positive shared signal at this locus in the scan were artificially increased. Because of this, the CARD15 locus was

The meta-analysis was performed using a directional non-weighed Z-score method as explained in the methods section. Combined analyses were performed using a directional weighed Z-score method within diseases and a directional non-weighed Z-score method between diseases. Results for the combined analysis are given only for the SNPs that pass the replication thresholds (directionality in each disease and p-value <0.0071 for the combined replication data).

**,** OR for the replication is reported for the allele identified as the risk allele in the initial scan; *, SNPs that were imputed in the CeD replication datasets.

N.T., not tested. CeD = Celiac disease, CD = Crohn’s disease, SNP = single nucleotide polymorphism, IL18RAP = interleukin 18 receptor accessory protein, PTPN2 = protein tyrosine phosphatase, PUS10 = pseudouridylate synthase 10, KCNG4 = potassium voltage-gated channel, subfamily G, member 4, non-receptor type 2, C10orf72 = Chromosome 10 open reading frame 72, FERM1 = -fermitin family homolog 1, 3q13, 9q13, 17p13 = intergenic regions.

doi:10.1371/journal.pgen.1001283.t001

Discussion

By performing a meta-analysis of GWAS data from CD and CeD as a single disease phenotype, we have identified four risk loci shared by these 2 diseases: PTPN2, IL18RAP, TAGAP and PUS10. This meta-analysis approach provided the power, lacking in individual disease-specific GWAS datasets, to identify shared risk loci with small effects in each single disease. This approach is a powerful and versatile way of identifying shared risk loci. In fact, two of the shared loci described here, TAGAP and PUS10, would not have reached genome-wide significance without the power gained from the combined samples (scan and replication) of these 2 diseases. As the GWAS for the individual diseases increase in power, we can expect the power of the current approach to also increase enabling us to identify further shared loci.

The TAGAP locus identified in the current study as a shared risk factor for CD and CeD is located on chromosome 6q25.3, within a 200-kb block of linkage disequilibrium (LD). This TAGAP locus was previously identified as a CeD risk locus [9] but not found in previous studies of CD. TAGAP is the best candidate of four genes in this region of strong LD [9]. TAGAP is a member of the Rho-GTPase protein family, which release GTP from GTP-bound Rho, thereby acting as a molecular switch. The gene is expressed in activated T cells and appears to be important for modulating cytoskeletal changes [14]. Little is known about the...
exact role of \textit{TAGAP} in immune function, but it has been found to be co-regulated with \textit{I22} and is expected to play a role in T-cell activation [14].

The current study also identifies a shared risk locus between CD and CelD in the \textit{PUS10} gene region, a locus previously described as a risk locus for CD [15]. This locus was recently identified as a risk locus in both ulcerative colitis (UC) and CelD, indicating that this locus may be a shared risk locus for these three diseases [7,16]. This latter finding further validates the approach used in this study to identify risk factors that are shared across diseases. Interestingly, the UC study identified three independent signals in this region which seem to be shared differently across these three diseases: one signal seems to be shared only between CD and UC, a second only between CelD and UC, while the third, identified in the current study, seems shared between all three diseases. Further analysis of this locus will be necessary in order to clarify the role of these different alleles in disease risk.

In this study we aimed to find shared genetic risk factors for CelD and CD by meta-analysis of GWAS data of both diseases, defining a single phenotype for these analyses. Using readily available data, we were able to reliably establish four shared loci: \textit{PTPN2, IL18RAP, TAGAP} and \textit{PUS10}. For many diseases with overlapping phenotypic characteristics, GWAS data is available and joint analysis of GWAS datasets of these related diseases could lead to the identification of many new shared susceptibility loci.

**Materials and Methods**

**Subjects**

For the CD aspect of the meta-analysis, we used the previously published data (available at http://www.broadinstitute.org/~jcbarrat/iibd-meta/) from the International Inflammatory Bowel Disease Genetics Consortium (IIBDGC) meta-analysis of 3230 CD cases and 4829 healthy controls taken from three independent CD GWAS (Table S1) [15]. A more in depth description of these cohorts and their origin can be obtained from the original publication of this meta-analysis.

Two independent cohorts were used for the CD replication phase (Table S1). The first consisted of 1217 Dutch CD cases from three Dutch university medical centers: the Academic Medical Centre Amsterdam (n = 661), the University Medical Centre Groningen (n = 322) and the University Medical Centre Leiden (n = 234); the 804 Dutch controls used for this replication cohort were obtained from cohorts of healthy partners of IBD patients from the UMC Leiden (n = 151) and the UMC Groningen (n = 120) and from healthy blood donors recruited through the Sanquin Blood bank by the UMC Utrecht and the VUMC Amsterdam (n = 533) [17,18]. The second replication cohort consisted of an Italian IBD case- control cohort (724 CD patients and 892 controls) collected at the S. Giovanni Rotondo “CSS” Hospital in Italy. This cohort has previously been used and characterized in several association reports [19,20].

All patients and controls were of European Caucasian descent. The diagnosis of CD required objective evidence of inflammation from radiologic, endoscopic, and/or histopathologic evaluation. All affected subjects fulfilled clinical criteria for CD. Recruitment of study subjects was approved by local and national institutional review boards, and informed consent was obtained from all participants.

For the celiac disease aspect of this meta-analysis, data from a previously published genome-wide scan (768 British cases, 1422 British controls) for CelD was used (Table S1). A more in depth description of this cohorts and its origin can be obtained from the original publications [9,12].

For the replication phase in CelD we used the genotyping results from a second celiac GWAS in three independent CelD cohorts (Table S1). From this study we received data from 3149 cases and 4714 controls from three European populations (UK, the Netherlands and Italy) genotyped on Custom Illumina Human 670-Quad, Hap550 and 1.2 M slides [13]. UK CelD cases were recruited from hospital outpatient clinics (n = 434) and directly through Coeliac UK advertisement (n = 1415) [9]; UK controls were recruited from the 1958 birth cohort and UK National Blood Service for the Welcome Trust Case Control Consortium (WTCCC) (n = 3786). Dutch CelD cases were collected by the UMC Utrecht, Leiden UMC and VUMC Amsterdam from outpatient clinics (n = 803); Dutch controls were recruited through the Sanquin Blood bank by the UMC Utrecht and the VUMC Amsterdam (n = 385). Italian CelD cases (n = 497) and controls (n = 543) were collected by a CelD referral centre (Centro per la prevenzione e diagnosi della malattia celiaca, Fondazione IRCCS Ospedale Maggiore Policlinico) in northern Italy.

All affected individuals were unrelated and were diagnosed according to the revised ESPGAN criteria (1990). The cohorts encompassed individuals that showed a Marsh II or Marsh III lesion in the initial diagnostic small-bowel biopsy specimens, or presented with dermatitis herpetiformis and were \textit{HLA-DQ2} positive. Recruitment of study subjects was approved by local and national institutional review boards, and informed consent was obtained from all participants. Some controls were shared between the WTCCC component of the CD meta-analysis and the two UK CelD cohorts (one used in the original scan and one used as replication). This was taken into account as explained in the meta-analysis description.

**Imputation of GWAS data**

Imputation of the CelD datasets used in the initial and the replication phases of this study were performed with BEAGLE using HapMap phase II and HapMap phase III as reference datasets [21]. A minimum quality score for statistical certainty of the imputation of 0.98 was adhered to.

Imputation of the CD dataset for the initial CD-CelD meta-analysis was performed with the programs MACH and IMPUTE, using HapMap phase II as a reference dataset, as previously described [15,22,23].

**Meta-analysis**

For the original CD dataset, association tests were described previously [15]. Briefly, results for each SNP from three independent GWAS were summarized as Z-scores and combined in a weighted fashion into a single test statistic; imputation uncertainty was taken into account into Z-score and weight calculation using empirical variance calculated from allele dosage. For the original CelD GWAS scan, best guess imputed genotype frequency data was obtained, and association P-values were calculated using chi-square tests (1 df) of SNP allele counts.

The initial meta-analysis was performed using the statistical program R (http://www.r-project.org/). For both the CD and the CelD dataset the p-values signifying the evidence for association were converted to directionall Z-scores, and an overall Z-score and two-tailed p-value for the average of the individuals was subsequently calculated. Given the fact that some controls were shared between one component of the CD meta-analysis and the CelD scan, we expect a correlation of 0.187 between CD and CelD Z-scores. We took this correlation into account in the variance term of the overall Z-score [24].

Unweighed Z-scores were used when combining the data from CD and CelD in the initial meta-analysis, since the CD cohort was...
A locus was selected for replication when SNPs met the following criteria: a p-value for the locus of $<1 \times 10^{-5}$ in the meta-
analysis, in combination with a p-value of $<1 \times 10^{-2}$ in the CelD
dataset and a p-value of $<1 \times 10^{-3}$ in the CD dataset. Different
thresholds for CD and CelD for inclusion in the replication phase
were used in order to reflect the difference in power between the
scans for the two phenotypes. For each of the loci that met these
criteria, the most strongly associated SNP was analyzed in the CD
and CelD replication cohorts.

In order to evaluate the expected number of SNPs that would
pass our thresholds (p-value $<1 \times 10^{-5}$, $<1 \times 10^{-3}$, and $<1 \times 10^{-5}$
for CelD, CD and meta-analysis, respectively) by chance, we first
evaluated the probability for a particular SNP to reach those
thresholds under the null hypothesis of no association and the
expected correlation between the two datasets. This probability can
be evaluated from the distribution of two correlated normal
variables (correlation of 0.186), combined as described for the
meta-analysis. We evaluated this probability to be approximately
$6.0 \times 10^{-6}$. If the 468,378 SNPs tested in the scan were independent,
we would then expect less than 3 ($468,378 \times 0.186 \times 6.0 \times 10^{-6}$)
independent SNPs to be selected by chance. Under a binomial model, we
evaluated the probability that 9 or more independent SNPs passes
our thresholds to be lower than 0.0025. Those are obviously upper
bounds, as we know correlation exists among the SNPs tested.

Replication phase

For replication in CD, SNPs selected for testing were designed
into multiplex assays, and genotyped using primer extension
chemistry and mass spectrometric analysis (iPlex assay, Sequenom,
San Diego, California, USA) on the Sequenom MassArray. This was
performed at the Laboratory for Genetics and Genomic Medicine of
Inflammation (www.inflammgen.org) of the Université de Montréal.
Quality control was performed, excluding samples showing $>10\%$
missing data, as well as SNPs with $>10\%$ missing data or
significantly out of Hardy-Weinberg equilibrium (p-value $<0.001$).
The overall genotyping call rate in the CD replication dataset
following quality control analyses was $>99\%$. The CD replication
datasets from the two groups (Dutch and Italian) were combined and
analyzed using a weighted and directional Z-score approach.

For replication in CelD, genotype frequencies and association
data for five replication SNPs were obtained from genome-wide
genotyping datasets on Illumina Human 670Quad or 610Quad
Genotyping BeadChips (Illumina, Inc., San Diego, CA). Each
GWAS dataset was analyzed using PLINK 1.05 and association
p-values were calculated using chi-square tests (1 df) of SNP allele
counts [25]. Two of the replication SNPs were not included on the
Illumina Human 670Quad or 610Quad Genotyping BeadChips. For these
SNPs best guess genotype frequency data was obtained by
imputation as described above, and association p-values were

calculated using chi-square tests (1 df) of SNP allele counts The
CelD replication datasets from the three groups (UK, the
Netherlands and Italy) were combined and analyzed using a
weighted and directional Z-score approach.

Since selection of specific SNPs for replication was based on
their association p-values in the combined CD-CelD dataset, a
significant threshold for replication was set at a Bonferroni
corrected p-value of $0.05$ for 7 independent tests (p-value more
significant than 0.0071) in the combined CD-CelD replication
dataset. As for the initial meta-analysis, the data from the
replication in the CD and CelD cohorts were combined through an
unweighed Z-score approach. In addition, for a SNP to be
replicated, both effect and direction of association trend needed to
match between scan and replication within each disease.

For each SNP showing positive replication, an overall disease-
specific association p-value, combining the scan and replication
data, was also calculated using a weighted meta-analysis approach.
Finally, an overall CD-Celiac meta-analysis of the scan and
replication phases of this study was obtained, by combining these
within-CD and within-Celiac datasets in an unweighed meta-
analysis. Given the fact that some controls were shared between
the within-CD and the within-CelD, we expect a correlation of
0.149 between CD and CelD Z-scores. As for the initial scan, we
took this correlation into account in the variance term of the
overall Z-score as per Lin and colleagues [24].

Supporting information

Figure S1 Q-Q plot of meta-analysis scan. A meta-analysis scan
of 471,504 SNPs from genomewide datasets of CD and CelD was
performed using a directional non-weighed Z-score method (as
explained in the methods section). The Q-Q plot was generated from
the p-values for single-SNP Z scores. Given the strength of associ-
ation signal for the MHC region (chr6:27,100,000,35,000,000) in
CelD, this region overwhelmed the Q-Q plot and was therefore
removed from the dataset for purpose of clarity; removing the MHC
region had little impact on the observed inflation.

Acknowledgments

The authors would like to acknowledge the use of the published results
from the International Inflammatory Bowel Disease Genetics Consortium
(IIBDGC) meta-analysis of 3,230 CD cases and 4,829 healthy controls
taken from three independent CD GWA (results available at http://www.
broadinstitute.org/~jcbarret/ibd-meta/). We acknowledge use of DNA
from the British 1958 Birth Cohort collection. We thank all clinicians and
Coeliac UK for assistance with direct recruitment of celiac disease
individuals. We thank C. J. J. Mulder, M. L. Mearin, W. H. M. Verbeek,
samples. We thank A. Andriulli, F. Bossa, D. Scimeca, and A. Latiano for
collection of Italian CD samples. We thank P. Debuquas, R. Gwilliam, and
the Wellcome Trust Sanger Institute for UK control genotyping. We thank
K. Hunt, V. Mistry, and G. Heap for sample preparation; A. Curtotti and
C. Mein for assistance with UK case genotyping. This study makes use of
individuals. We thank C. J. J. Mulder, M. L. Mearin, W. H. M. Verbeek,
samples. We thank A. Andriulli, F. Bossa, D. Scimeca, and A. Latiano for
collection of Italian CD samples. We thank P. Debuquas, R. Gwilliam, and
the Wellcome Trust Sanger Institute for UK control genotyping. We thank
K. Hunt, V. Mistry, and G. Heap for sample preparation; A. Curtotti and
C. Mein for assistance with UK case genotyping. This study makes use of
Author Contributions
Conceived and designed the experiments: EAMF PG TG MJJD CW JDR. Performed the experiments: CB PCD CL DAvH. Analyzed the data: EAMF PG TG GB CB GT PCD CL DAvH MJD CW JDR. Contributed reagents/materials/analysis tools: PCFS DWH DB OP VA DAvH RKW CW JDR. Wrote the paper: EAMF PG TG GB RKW MJD CW JDR.
