Frontiers in Physiology 2014 Apr 23;5:157
ABSTRACT

Rationale
A critical reduction in central blood volume (CBV) is often characterized by hemodynamic instability. Restoration of a volume deficit may be established by goal-directed fluid therapy guided by respiration-related variation in systolic- and pulse pressure (SPV and PPV). Stroke volume index (SVI) serves as a surrogate end-point of a fluid challenge but tissue perfusion itself has not been addressed.

Objective
To delineate the relationship between arterial pressure variations, SVI and regional brain perfusion during CBV depletion and repletion in spontaneously breathing volunteers.

Methods
This study quantified in 14 healthy subjects (11 male) the effects of CBV depletion (by 30° and 70° passive head-up tilt; HUT) and a fluid challenge (by tilt back) on CBV (thoracic admittance), mean middle cerebral artery (MCA) blood flow velocity (CBF\textsubscript{mean}), SVI, cardiac index (CI), PPV and SPV.

Results
PPV (103±89%, p<0.05) and SPV (136±117%, p<0.05) increased with progression of central hypovolemia manifested by a reduction in thoracic admittance (11±5%, p<0.001), SVI (28±6%, p<0.001), CI (6±8%, p<0.001) and CBF\textsubscript{mean} (17±7%, p<0.05) but not in arterial pressure. The reduction in CBF\textsubscript{mean} correlated to the fall in SVI (R\textsuperscript{2}=0.52, p<0.0001) and inversely to PPV and SPV (R\textsuperscript{2}=0.46 (p<0.0001) and R\textsuperscript{2}=0.45 (p<0.0001), respectively). PPV and SPV predicted a ≥15% reduction in CBF\textsubscript{mean} and SVI with comparable sensitivity (67%/ 67% vs. 63%/ 68% respectively) and specificity (89%/94% vs. 89%/94%, respectively). A rapid fluid challenge by tilt-back restored all parameters to baseline values within one minute.

Conclusion
In spontaneously breathing subjects, a reduction in CBF\textsubscript{mean} was related to an increase in PPV and SPV during graded CBV depletion and repletion. Specifically, PPV and SPV predicted changes in both SVI and CBF\textsubscript{mean} with comparable sensitivity and specificity, however the predictive value is limited in spontaneously breathing subjects.
INTRODUCTION

Severe hypovolemia is associated with a critical reduction in central blood volume (CBV) quite often related to hemorrhage or dehydration. This results in hemodynamic instability with a reduction in cardiac output (CO) and tissue oxygen delivery. Volume depletion is usually of acute onset, and neuro-cardiovascular control mechanisms including reflexes from high and low pressure area receptors initiate the body’s defending response. In contrast, in chronic hypovolemia, the capillary fluid shift transfers fluid to the intravascular space, whereas the humoro-cardiovascular and long-term renal blood volume control systems with a longer time constant come into operation.

Restoration of adequate tissue perfusion and oxygenation is of major importance in hemodynamically unstable patients. In anesthesia and intensive care medicine, establishing this therapeutic goal typically involves intravascular fluid administration as the cornerstone of treatment for central hypovolemia.

However, diagnosing a volume deficit is not straightforward. In present clinical practice, volume treatment is commonly adjusted by recordings of the heart rate (HR) and arterial blood pressure (BP). The experience is, however, that fluid infusion by focusing on these hemodynamic variables allows for wide variation in administered volume because neither BP nor HR accurately reflects changes in CBV. Observations in hypotensive patients during hemorrhage indicate that reversible hypotensive hypovolemic shock is in fact characterized by a decrease in heart rate reflecting an increase in vagal tone. Thus the sensitivity of HR as an early indicator is low and highly non-specific. This is further supported by data obtained in a human model of acute hypovolemic shock by either lower body negative pressure or passive head-up tilt. Also, clinical signs of hypovolemia including diminished skin turgor and high urine osmolarity do not accurately reflect reductions in CBV.

An increase in SV or CO in response to fluid therapy is considered favorable. A meta-analysis of 12 clinical studies showed that with current clinical practice, between 40-70% of critically ill patients are so-called responders. The substantial number of patients not responding to fluid therapy calls for physiological monitors capable of predicting fluid responsiveness. Respiration-related variations in left ventricular preload which are transferred to variations in arterial pressure (e.g. systolic pressure variation (SPV) and pulse pressure variation (PPV) are being introduced in clinical medicine as potentially useful tools to guide volume administration. In the majority of studies aiming for candidate indices predictive for fluid responsiveness, however, the investigated endpoint of a fluid challenge has been a change in SV (index; SVI) or CO / cardiac index (CI). Although SV and CO serve as surrogate end-points of a fluid challenge, brain perfusion as the actual therapeutic endpoint is as yet not being addressed by present research. The large metabolic needs of the brain reflected by respectively 20 and 25% of oxygen and
glucose consumption by neuronal activity renders it extremely sensitive to sufficient and uninterrupted blood supply. In this study, the hypothesis is tested that arterial pressure variations during progressive central hypovolemia relate to changes in brain perfusion. We therefore set out to gauge the relationship between arterial pressure variations, SVI and cerebral blood flow velocity during central blood volume depletion and repletion in spontaneously breathing subjects.

METHODS

Subjects
Fourteen healthy volunteers (11 male) with a median (range) age of 25 (23-37) year, height 180 (173-204) cm and weight 72 (62-86) kg, without taking any medication and/or history of regular fainting or cardiac arrhythmia participated in this study. Phase of menstrual cycle in female subjects was not accounted for. This study was approved by the institutional Medical Ethics Committee and took place in the Laboratory for Clinical Cardiovascular Physiology in the Academic Medical Center in Amsterdam. The subjects abstained from heavy physical exercise and caffeinated beverages 4 hours prior to the experiment. Diurnal variations in body fluid contents were accounted for by strictly adhering the experiment to the same hour of the day. All procedures and risks associated with the study were explained to the subjects and written informed consents were obtained.

Experimental protocol
Measurements were performed between 11 am and 3 pm in a quiet room with the subjects on a custom built computer controlled tilt table that minimizes muscle tensing and limits vestibular stimulation during tilting. Resting supine measurements represented normovolemic conditions. Next, subjects were head-up tilted (HUT) to respectively 30° and 70° causing progressive central hypovolemia of acute onset and subsequently tilted back to the supine position mimicking a rapid volume repletion. Following each angle change of the tilt table, that body position was maintained for five minutes to obtain a stable hemodynamic situation. The last 60 seconds of these adjustment periods were used for analysis. Following tilt-back to the supine position, the subjects rested again. Subsequently they were tilted in a sinusoidal fashion (tilting frequency varying from 0.042-0.2 Hz or 5-12 min⁻¹) enhancing blood pressure variation for evaluation of cerebrovascular autoregulatory efficacy. The breathing was paced at 13 breaths per minute by auditory support. This breathing frequency was continued throughout the sinusoidal tilts, to separate the influence of gravity and the influence of respiration on the measured cardiovascular signals.
Measurements

Continuous arterial blood pressure (BP) was non-invasively measured (Nexfin, Edwards Lifesciences BMEYE, Amsterdam, the Netherlands) using the volume clamp method. A finger cuff fastened on the middle finger was held at heart level. A pulse contour method (Nexfin CO-trek, Edwards Lifesciences BMEYE, Amsterdam, the Netherlands), adapted for age, gender, height and weight, provided left ventricular SV and CO by multiplying SV by instantaneous heart rate (HR). SVI and CI were SV and CO divided by body surface area. SPV and PPV were calculated per breath from the BP signal according to Eq. 4.4.1 (Chapter 4.4). Arterial pressure variations were calculated per breath and then averaged over five consecutive breaths (see Figure 2.1.2, Chapter 2).

Cerebral perfusion pressure (CPP) was determined by subtracting critical closing pressure (CrCP) from BP at brain level. BP at brain level was estimated by subtracting hydrostatic difference between the finger cuff and the level of transcranial insonation by Transcranial Doppler (TCD) ultrasonography and CrCP was estimated by first harmonic Fourier filtered normal arterial pressure and velocity wave heart beat data as described by Aaslid et al. Regional brain perfusion of the anterior circulation was investigated by the assessment of mean middle cerebral artery (MCA) blood flow velocity (CBFv_mean) followed in the proximal segments by means of TCD (DWL Multidop X4, Sipplingen, Germany). The MCA was insonated through the temporal window just above the zygomatic arch at a depth of 40-60 mm with a pulsed 2 MHz probe. After the Doppler signal was optimized, the probe was attached to the skull in a fixed angle by means of a head-band.

The HUT induced translocation of CBV to the lower extremities was monitored by electrical impedance plethysmography (350 μA at 50 kHz; Nihon Kohden, AI-601G, Japan) measured at the level of the thorax and expressed as changes in thoracic admittance. Airway flow and pressure were measured by means of the Alveotest flowmeter (Jaeger, Würzburg, Germany) and end-tidal CO₂ partial pressure (PetCO₂) was measured using a capnograph (Tonocap, Datex-Ohmeda, Madison, USA). Tidal volume (TV) was calculated by integration of the flow signal. All data were sampled at 200 Hz and collected using an Analog Devices RT1815 PC-card with custom made software. Signals were visually inspected for artifacts and analyzed offline (Matlab R2007b, Mathworks Inc. MA, USA).

Dynamic cerebral autoregulation (CA) was quantified as the counter-regulatory capacity to maintain CBFv_mean during oscillatory tilt induced changes in BP. Dynamic CA was assessed by means of cross-spectral density analysis of beat-to-beat data of MAP at brain level and CBFv_mean after spline interpolation and resampling at 4 Hz. Gain and phase were obtained for the frequencies equal to the oscillatory tilt frequencies (ranging from 0.042-0.2 Hz). The gain reflects the effective amplitude dampening of BP fluctuations and phase shift was defined positive where CBFv_mean leads MAP at brain level. Coherence examined the strength of the relationship between MAP and CBFv_mean. To account for
inter-subject variability, the gain was normalized for MAP and CBF$_{\text{mean}}$ and expressed as the percentage change in cm·sec$^{-1}$ per percentage change in mmHg.$^{64}$

**Statistical analysis**

Results are presented as mean ± SD. The effect of HUT on measured parameters was assessed using a One Way Repeated Measures Analysis of Variance (ANOVA) test together with the Holm-Sidak method to perform pairwise multiple comparisons. When data were not normally distributed, they are presented as medians and range and non-parametric statistical tests were used.

Linear Mixed Model analysis was performed (IBM SPSS statistics 20, IBM corporation, USA) to examine the relation between brain perfusion (referred to as dependent variable) and hemodynamic and respiratory variables (fixed covariates). R square was calculated according to the following formula:

$$R^2 = 1 - \frac{\sum(y_i - f_i)^2}{\sum(y_i - \bar{y})^2}$$  

Eq. 6.1.1

where $y$ and $f$ refers to, respectively, the observed and predicted values.$^{403}$ A multivariate, stepwise regression model was constructed with CBF$_{\text{mean}}$ as the dependent variable and mean arterial pressure at heart level (MAP), CPP, SVI, HR, total peripheral resistance (TPR), PetCO$_2$ and thoracic admittance as the independent variables.$^{404}$ The model was developed by forward entry and removal of the independent variables according to their significant contribution (according to the F-test) in explaining the variance in the dependent variable. Baseline measurements for both the dependent as independent variables were normalized to zero and the effect of tilt was expressed as absolute change with respect to the baseline value.

The subjects were divided into two groups according to the percent decrease in SVI or CBF$_{\text{mean}}$ during progressive CBV depletion related to the resting supine value. A 15% increase in SVI in response to fluid infusion is considered clinically relevant according to previously published criteria.$^{127,255,256,405}$ In this study, subjects with >15% decrease in SVI or CBF$_{\text{mean}}$ were classified as having a central blood volume deficit. Receiver operating characteristics (ROC) curves evaluated the predictive value of PPV and SPV on volume deficits by determination of sensitivity and specificity values and its corresponding optimal threshold value.$^{406}$ Accuracy was assessed by the area under the curve (AUC) values presented as area ± SD. A p-value less than 0.05 was considered to indicate a statistically significant difference.
RESULTS

All subjects completed the protocol. Figure 6.1.1, Figure 6.1.2 and Table 6.1.1 summarize the hemodynamic and brain perfusion response to graded HUT and tilt back.

Data are presented as mean ± SD. MAP, mean arterial pressure; SAP, systolic arterial pressure; DAP, diastolic arterial pressure; PP, pulse pressure; CPP, cerebral perfusion pressure; HR, heart rate; SVI, stroke volume index; Cl, cardiac index; T.adm., thoracic admittance; TPR, total peripheral resistance; CBFVmean, mean middle cerebral artery blood flow velocity; PPV, pulse pressure variation; SPV, systolic pressure variation; TV, tidal volume; PetCO₂, end-tidal CO₂ partial pressure. *p<0.05 with respect to the previous tilt position, ‡p<0.05 volume repletion vs. baseline supine position.

Central blood volume depletion (HUT)

MAP and SAP remained constant while DAP increased (11±12%, p<0.001) with 70° HUT resulting in a 19±11% (p<0.001) reduction in PP. Although a decrease in CPP was demonstrated during HUT, this was not significantly different from the supine position. SVI (28±6%, p<0.001), thoracic admittance (11±5%, p<0.001) and CBFVmean (17±7%, p<0.05) declined while an increase was seen in HR (32±14%, p<0.001). Cl declined (6±8%, p<0.001) and TPR increased (10±11%, p<0.001) only from supine to 30° without further change at 70° HUT. PPV and SPV did not change from supine to 30° HUT but substantially increased (103±89% (p<0.05) and 136±117% (p<0.05), respectively) with 70° HUT. TV and breathing frequency did not change during HUT vs. the supine position while PetCO₂ declined (8±11%, p<0.001) with 70° HUT.

Central blood volume repletion (tilt back)

Every changing parameter returned to baseline values following tilt back except TPR which remained elevated compared to the baseline measurement (p<0.05, Table 6.1.1).
Cerebral blood flow velocity and stroke volume

Forward stepwise regression analysis revealed that absolute change in CBFv\textsubscript{mean} was mainly predicted by absolute change in SVI ($r^2=0.53$, $p<0.001$). Absolute change in PetCO\textsubscript{2} was secondly added to this prediction model, resulting in a slightly stronger regression ($r^2=0.57$, $p<0.001$). Single linear plots of the dependent variable (CBFv\textsubscript{mean}) and its strongest prediction variable (SVI) are shown in Figure 6.1.3. There was only a weak relation between CPP and CBFv\textsubscript{mean} ($r^2=0.16$, $p=0.007$; Figure 6.1.4). The median (range) of individual correlation coefficients for the relation between SVI and CBFv\textsubscript{mean} and for CPP and CBFv\textsubscript{mean} was: $r^2=0.902$ (0.059-0.999) and $r^2=0.345$ (-0.672-0.998) respectively.

Figure 6.1.3. Linear regression plot of absolute change in CBFv\textsubscript{mean} and SVI. All subjects contributed three points in each regression line (during 30° and 70° HUT + 0° HUT after tilt back). The regression function is equal to $y=-0.12+0.52x$ with corresponding correlation coefficient of $r^2=0.53$ ($p<0.0001$). CBFv\textsubscript{mean} mean middle cerebral artery blood flow velocity; SVI, stroke volume index.
Arterial pressure variations and brain perfusion

Figure 6.1.4. Single linear regression plot of absolute change in CBF$_{\text{mean}}$ and CPP. All subjects contributed three points in each regression line (during 30° and 70° HUT + 0° HUT after tilt back). The regression function is equal to $y=-1.673-0.28x$ with corresponding correlation coefficient of $r^2=0.16$ ($p=0.007$). CBF$_{\text{mean}}$, mean middle cerebral artery blood flow velocity; CPP, cerebral perfusion pressure.

Arterial pressure variations

Figure 6.1.5, panel (A) displays single linear regression plots between ΔSVI and ΔPPV or ΔSPV. Regression analysis between ΔSVI and ΔPPV/ΔSPV showed linear correlations (PPV: $r^2=0.74$, $p<0.0001$ and SPV: $r^2=0.76$, $p<0.0001$) with a higher slope for ΔPPV compared to ΔSPV. Single linear regression analysis was also applied on ΔCBF$_{\text{mean}}$ and ΔPPV or ΔSPV (see panel (B) of Figure 6.1.5). Correlations were seen between ΔPPV/ΔSPV and ΔCBF$_{\text{mean}}$ (PPV: $r^2=0.46$, $p<0.0001$ and SPV: $r^2=0.43$, $p<0.0001$). The slope of the regression plots for both ΔPPV and ΔSPV were comparable with those between ΔPPV/ΔSPV and ΔSVI. Again, the highest slope was seen for ΔPPV.

Dynamic CA

The CBFVmean-to-MAP at brain level transfer functions displayed the expected high-pass filter characteristics of dynamic autoregulation, with a decrease in phase lead and increase in normalized gain with increasing sinusoidal tilt frequency Figure 6.1.8). Phase lead and gain at 0.1 Hz were, respectively, 45 degrees and 0.89%·%⁻¹.

DISCUSSION

The main new finding of this study is that in spontaneously breathing subjects under conditions of depletion and repletion of central blood volume, CBF$_{\text{v,mean}}$ was linearly related to arterial pressure variations. Specifically, arterial pressure variations predicted a decline in CBF$_{\text{v,mean}}$ and SVI with comparable sensitivity and specificity.

Posture and central blood volume depletion

Clinically, hypovolemia is manifested by a reduced CBV. With passive HUT, approximately 700 ml of central blood volume redistributes from the chest into the gravitational dependent regions, largely contained in the venous compartment and therefore not contributing effectively to the circulating blood volume.\[^{31,147}\] In this study, a postural reduction in CBV coincided with a decline in SVI.\[^{200,262,407,408}\] This is attributed to blood pooling in the lower parts of the body and to a reduction in venous return which is in agreement with data from earlier studies.\[^{33,261}\] Constant values of MAP by a baroreflex mediated increase in TPR counterbalancing the postural reduction in SVI and CI illustrates the contention that MAP does not reflect changes in CBV.\[^{117,409}\]

Posture and PCO$_2$

Increased ventilation and corresponding lowering of arterial carbon dioxide partial pressure (PaCO$_2$) associated with postural stress, is considered to be contributory to the reduction in CBF$_{\text{v,mean}}$.\[^{410-412}\] The mechanisms that drive breathing during postural stress are not well understood but likely find their origin in both the brain and the periphery. We earlier considered that in the upright position the larger BP variability and less stable blood flow enhance fluctuation of PaCO$_2$ as an input signal to the carotid body chemoreceptors.\[^{73}\] The interaction of enhanced baroreceptor activity and carotid body chemoreceptor stimulation may modify the respiratory drive.\[^{413,414}\] Arterial hypocapnia has been associated with orthostatic intolerance and lowering of PaCO$_2$ may reduce the prevailing peripheral vasomotor tone.\[^{415}\] Thus, the postural reduction in PetCO$_2$ suggests a contribution of mild hypocapnia to the reduction in cerebral perfusion. We consider that PetCO$_2$ tracks changes in PaCO$_2$ in a fixed body position only, whereas the PaCO$_2$-to-PetCO$_2$ gradient is enhanced by the postural reduction in CO. This results in an increased $V_f/Q$ ratio,\[^{210,211,416}\] with overestimation of the the reduction in P$_a$CO$_2$.\[^{33,211}\] Also, when during passive head-up tilt PetCO$_2$ is clamped to the level in the supine position, CBF$_{\text{v,mean}}$ declines in the first minute of tilt only. Afterwards the postural reduction in CBF$_{\text{v,mean}}$ has become independent of the ~4 mmHg reduction in PetCO$_2$ for at least 5 min in the 70° HUT position.\[^{33}\] In the present study, postural stress, duration of tilt and reduction in PetCO$_2$ were comparable to the unclamped limb in that study supporting that the decrease in PetCO$_2$ during HUT does not explain the reduction seen in CBF$_{\text{v,mean}}$.\[^{33}\]
Posture and cerebrovascular autoregulation

The decline in CPP is explained by the HUT induced hydrostatic pressure gradient when the cerebral circulation is positioned above the level of the heart. According to the traditional concept of CA, cerebral blood flow (CBF) is maintained more or less constant in the face of changing CPP. Nevertheless, postural stress elicits reductions in indices of CBF irrespective of the fact that CPP remains within the so called autoregulatory range, challenging the concept of CA as a plateau. In fact, constant CBF would require an infinite gain which is generally not operative in humans. Assessment of CA is based on introducing CPP fluctuations and quantifying their transfer to the blood velocity in a large cerebral artery in terms of phase angle and gain. This approach addresses specifically the dynamic component of CA. CA is, however, considered to encompass both static (long-term) and dynamic (short-term) components. It remains unclear whether short- and long-term regulation of CBF are separate mechanistic entities. Reference values have not been defined and overlap exists between healthy subjects vs. patients with impaired dynamic CA. We demonstrated the expected high-pass filter characteristics and therefore assume that in the young adult subjects in this study dCA was intact. However, CA integrity does in itself not preclude some influence of the postural reduction in CPP on CBF\textsubscript{mean}. Of interest, the postural reduction in CPP was only minor and the correlation between changes in CPP and CBF\textsubscript{mean} weak, supporting that the effect of the reduction in CPP on CBF\textsubscript{mean}, if anything, must have been limited.

Cerebral blood flow velocity and stroke volume

Cerebral blood flow velocity and its relation with CO has been investigated in several studies. Under conditions of 30 Torr lower body negative pressure\textsuperscript{418} and HUT,\textsuperscript{185} both CO and CBF\textsubscript{mean} decreased whereas in response to moderate exercise,\textsuperscript{419,420} CO and CBF\textsubscript{mean} increase together with CBV without changes in PaCO\textsubscript{2}. In this study, the change in CI from supine to 30° HUT was limited. From 30° to 70° HUT, SVI and CBV decreased further but CO was maintained, probably attributable to the baroreflex mediated increase in HR. During progressive central hypovolemia a reduction in CBF\textsubscript{mean} coincided with the fall in SVI, and vice versa CBF\textsubscript{mean} and SVI both increased in response to a simulated fluid challenge by repositioning from upright to supine, supporting a dependency of CBF\textsubscript{mean} on CBV. Furthermore, SVI appeared to be the strongest hemodynamic predictor for changes in CBF\textsubscript{mean}. Collectively, these findings suggest that in spontaneously breathing volunteers subjected to simulated progressive central hypovolemia, changes in SVI reflect those in CBF\textsubscript{mean} in a linear manner (see Figure 6.1.3).

Predictive value of arterial pressure variations

During surgery or in an intensive care setting, an increase in SVI in response to fluid administration in the anesthetized patient is considered to indicate fluid responsive-
ness. This study demonstrated an increase in arterial pressure variations in response to a clinical relevant decrease in SVI during HUT and vice versa during tilt back. This strong correlation between SVI and arterial pressure variations is in agreement with earlier research. A new finding is that under the conditions of this study CBFv_{mean} and arterial pressure variations are related too. Although arterial pressure variations have been proven valuable to predict fluid responsiveness in patients receiving mechanical ventilation, their predictive value in spontaneously breathing patients is lower. Our findings are in agreement with these data, whereas the present study extends this knowledge by demonstrating that arterial pressure variations predict changes in CBFv_{mean} with comparable sensitivity and specificity values, and a higher accuracy during graded hypovolemia. Extrapolating this to clinical practice, a fluid challenge targeting SVI also targets brain perfusion.

Limitations

Potential limitations inherent to the study design should be considered. Transcranial Doppler ultrasonography is used to monitor changes in cerebral blood flow. This technique has been widely used under the assumption that the cross-sectional area of the MCA is maintained during the measurement. Possible changes in the diameter of the insonated vessel by enhanced sympathetic activity could modulate velocity independently of flow. Previous research showed that increases in sympathetic outflow by baroreflex disengagement or chemoreflex activation do not alter MCA diameter, and we therefore assume that a constant MCA diameter links changes in cerebral blood velocity to changes in flow.

Detecting a volume deficit is considered as the major goal of determining fluid responsiveness. However, recent studies indicate that under certain conditions fluid bolus administration is associated with an increased mortality. It is recognized that fluid administration should be practiced with much greater caution and increased vigilance and a more conservative fluid management seems appropriate. The values represented in Table 6.1.2 are therefore optimized for high specificity rather than high sensitivity.

In summary, the present study shows for the first time in awake humans subjected to progressive central hypovolemia that arterial pressure variations are related to both cerebral blood flow velocity and SVI. Specifically, PPV and SPV predicted changes in both SVI and CBFv_{mean} with comparable sensitivity and specificity, however the predictive value is limited in spontaneously breathing subjects.
