ABSTRACT

Aims. We aim to study the composition and energetics of the circumstellar material of DK Cha, an intermediate-mass star in transition from an embedded configuration to a star plus disk stage, during this pivotal stage of its evolution.

Methods. Using the range scan mode of PACS on the Herschel Space Observatory, we obtained a spectrum of DK Cha from 55 to 210 μm as part of the DIGIT key program.

Results. Almost 50 molecular and atomic lines were detected, many more than the 7 lines detected in ISO-LWS. Nearly the entire ladder of CO and ionic emission lines in the far-infrared reveal the outflow’s influence on the envelope. The inferred hot gas may be photon-heated, but some emission may be caused by C-shocks in the walls of the outflow cavity.

Key words. astrochemistry – circumstellar matter – stars: formation – stars: protostars – infrared: ISM – submillimeter: ISM

1. Introduction

One of the pivotal points in the formation of a star occurs when the star and disk system emerges from the collapsing envelope, signaling the end of the main accretion of stellar mass. The transition from a stage I protostar, embedded in a substantial envelope, to a stage II configuration, with only a star and disk1, is poorly understood.

At a distance of 178 ± 18 pc IRAS 12496-7650 is the brightest infrared (IR) and submillimeter (submm) source in the Chamaeleon II star-forming region, (Whittet et al. 1997). Follow-up studies to the discovery of IRAS 12496-7650 by Hughes et al. (1989, 1991), along with subsequent observations (e.g., Whittet et al. 1997; Young et al. 2005; Porras et al. 2007; Spezzi et al. 2008), identified the variable Herbig Ae star DK Cha as the optical counterpart. The central star mass is estimated to be 2–3 $M_\odot$ (Spezzi et al. 2008) with a bolometric luminosity between 24 (Spezzi et al. 2008) and 35 $L_\odot$ (van Kempen et al. 2009a). The star is surrounded by a molecular outflow and protostellar envelope (van Kempen et al. 2006; van Kempen et al. 2009a). The spectral energy distribution (SED) is roughly flat with wavelength from the near-infrared to mid-infrared (Hughes et al. 1989). Using the $T_{bol}$ definition and including longer wavelength data (e.g., Henning et al. 1993; van Kempen et al. 2009a), DK Cha has $T_{bol} = 580$ K, making it a class I source, but near the class II boundary at 650 K. Owing to an approximately face-on viewing angle down the outflow cone (van Kempen et al. 2009a), one can observe the protostellar disk directly, unobstructed by the surrounding envelope. This viewing angle also allows the optical emission to escape. The observational SED classes are often assumed to correspond to the physical stages, but this is by no means obvious when aspherical models are examined (e.g., Robitaille et al. 2007; Crapsi et al. 2008; Dunham et al. 2010) or tracers of dense gas are considered (van Kempen et al. 2009b). The same physical object can have different SED classifications depending on the viewing angle. Thus, it is interesting to study an object that is near an SED classification boundary and that also appears to be transitional in physical stage.

Strong far-IR continuum and line emission have been detected (Giannini et al. 1999; van Kempen et al. 2006). As discussed by van Dishoeck (2004); Nisini et al. (2005), and
van Kempen et al. (2010) for the similar source HH46, far-IR atomic, ionic, and molecular lines can constrain the properties of the disk, envelope, and outflow. The CO emission lines between \( J = 14-13 \) and \( J = 19-18 \), as well as [OI] and [CII], were observed from DK Cha with ISO-LWS, but other possible molecular species, such as OH and H$_2$O, were undetected (Lorenzetti et al. 1999; Giannini et al. 1999).

The large beam of ISO-LWS (90") and its low spectral resolving power (\( \Delta \lambda / \lambda = 200 \)) were insufficient to determine the origin (e.g., envelope versus outflow) of the CO emission. The preferred picture was of a small, quiescent hot core of \( \sim 300 \) AU around the protostar (Giannini et al. 1999), but observations of CO 4–3 and 7–6 indicate that this warm CO emission either originates outside the inner few thousand AU or cannot be heated simply by radiation from the central star (passive heating) (van Kempen et al. 2006); the far-IR and submm lines have different energies and critical densities, so they may originate in different regions.

The Herschel key programme Dust, Ice, and Gas In Time (DIGIT) aims to study the evolution of these three constituents through the star formation process by observing objects at different stages. This paper, along with a companion paper on HD100546, a stage II object (Sturm et al. 2010), present the first results from the DIGIT science demonstration observations.

2. Observations

The launch of the Herschel Space Observatory (Pilbratt 2010) with the Photodetector Array Camera and Spectrometer (PACS) instrument (Poglitsch 2010) onboard, enables the acquisition of far-IR spectra with high spectral resolving power and good spatial (\(~ 9") resolution. The range scan/SED mode provides a full spectrum (55–210 \( \mu m \)).

DK Cha was observed for a total of \sim 4 \, h on 10 December 2009 by the PACS spectrometer on the Herschel Space Observatory in pointed range-scan spectroscopy mode (obsid 1342188039 and 1342188040). An image slicer rearranges the light within a \( 5 \times 5 \) array, with each spatial pixel (spaxel) covering 9.4’ x 9.4’. A grating disperses the light onto two 16 x 25 pixel Ge:Ga detectors. Observations were taken using nodding, in which two off-positions separated by \( \sim 25 \) pixel are taken as “blank” sky, from which the signal is subtracted. Consequently, spatially diffuse lines (e.g., [CII]) are subtracted out.

The effective spectral resolving power was about 1000+/–500, lower than expected, because of the pointing error, which is perpendicular to the slit, and the effects of fringing on the continuum. The point-spread function of PACS increases towards longer wavelengths and is larger than a single spaxel, but is corrected in post-processing using the PACS spectra of the point-like HD100546 (Sturm et al. 2010) to calculate the extraction efficiencies.

The data were reduced using the Herschel interactive processing environment (HIPE v. 2.4). The observation was slightly mispointed (\sim 5–6") making it difficult to assess whether the emission is extended and causes wavelength shifts in some spectral ranges. Because of the mispointing, uncertainty in the spectral response function, light leakage problems, and uncertainties in the wavelength dependence of the PSF, the spectrum was trimmed shortward of 56 \( \mu m \), longward of 190 \( \mu m \), and in the range 95–101 \( \mu m \). Two spectra were used to identify lines: One from the central spaxel alone and a second spectrum, which was used for most lines, created by summing the fluxes from all spatial pixels to correct for the PSF and mispointing. We focus on gas lines in this Letter.
the transition from disk to envelope, and the PACS continuum arises in the envelope. The model underestimates the observations in the near-IR and mid-IR, indicating that the disk emission is underestimated in the model.

The best-fit models of the SED grid indeed confirm the assumption of a nearly face-on configuration <18° with relatively low and equal envelope and disk masses of 0.03 $M_\odot$, indicative of a source in transition from stage I to stage II (Robitaille et al. 2007). The PACS continuum was not used to constrain the fit, the consistency with the predicted model (differences of <10%) thus being encouraging, especially considering the calibration uncertainty of 30–50%.

3.2. Line inventory

Table 1 lists all gas lines that have been identified. Figure 2 shows the spectrum after subtraction of a polynomial fit to the continuum. We used a combination of the ISO line list and the list published in Lerat et al. (2006) for the Orion bar. More lines may be detectable in this spectrum after PSF deconvolution. Some lines in Table 1 are only detected in the central spaxel. Owing to the fringing in other spaxels at short wavelengths and the PSF problems discussed above, these lines cannot be seen in the summed result of Fig. 2. Using spectra from both the summation of all 25 spaxels and from only the central spaxel, a large range of CO, $H_2O$, and OH lines were detected, ranging in excitation energies from a few hundred kelvin to over 3000 K. In addition, [O I] and [N II] were identified. Emission from [C II] at 157.7 μm is not seen. That line was detected by Lorenzetti et al. (1999), but it was interpreted to be extended emission, associated with the galactic ISM. This component is subtracted out in our observations due to the nodding, which was not used in ISO-LWS.

3.3. Gas analysis

Infrared CO lines were previously detected by Giannini et al. (1999), but only up to CO J = 19–18. Assuming the lines to be optically thin, those could be fitted with temperatures ranging from $T = 200$ K to $T = 750$ K and densities from $n = 4 \times 10^6$ cm$^{-3}$ to $n = 5 \times 10^7$ cm$^{-3}$. The high T, low n model, which produces the most emission in the high-J lines, is overplotted in Fig. 3. As can be seen, this model severely underpredicts the intensity of the CO lines from higher transitions seen by Herschel. The other proposed models predict even less high-J emission.

The CO level populations up to J = 31 (Fig. 3), can be fitted with two distinct rotational temperatures ($T_{\text{rot}}$), a break occurring at about $E_{\text{sup}} = 1500$ K. Most of the mid-J CO lines can be fitted by $T_{\text{rot}} \sim 380$ K, while higher excitation lines are best fitted with $T_{\text{rot}} \sim 1365$ K. In HH46 (van Kempen et al. 2010), UV photon heating (Spaans et al. 1995) predominates for lines with energies below 1700 K, while a non-dissociative C-shock has a more important effect than the emission from higher excitation lines. A similar model is plausible for DK Cha, but this issue will be explored in a forthcoming paper (Green et al. in prep).

Water was detected in a wide variety of transitions, up to $\theta_{27}$–$6_{10}$ at 71.93 μm with ($E/k = 843$ K). Water was not detected in ISO-LWS (Giannini et al. 1999) because the lines are 5 times weaker than the CO lines. The discovery of the $\theta_{27}$–$6_{10}$ line is indicative of high temperature, as confirmed by the high-J CO lines. Given the possible identification of shocked CO and the geometry of DK Cha, it is likely that the water emission arises at least in part from either a non-dissociative C-shock or UV-heating of the quiescent material along the outflow cavity walls.

In addition, at least 9 lines of OH are detected. Since oxygen is rapidly transformed into $H_2O$ at temperatures higher than 100 K and frozen out below that, either a very strong UV field or a dissociative shock is needed. OH is a major coolant for dissociative shocks (Neufeld & Dalgarno 1989). This dissociative shock is accompanied by a C-shock, which may explain the CO and $H_2O$ analysis. Models from Wampfler et al. (in prep) also suggest that C-shock densities are often too low to account for both these high excitation lines and at the same time not over-produce the 119 and 163 μm OH lines.

HD 100546 (Sturm et al. 2010), a Herbig Be star without an envelope, was chosen for early observations to be a source analogous to DK Cha, but more evolved. A comparison is useful because similar species are seen in its spectrum. Emission of $H_2O$ and OH from the upper layers of a flared, but quiescent disk, similar to that around HD 100546 (Sturm et al. 2010), may account for some of the lines from DK Cha. However, accounting for the difference in distance, the CO lines from DK Cha are more than 10 times stronger, and higher excitation lines from $H_2O$ are seen toward DK Cha.

A possible explanation of the stronger emission of DK Cha is an accretion shock onto the disk, where high densities and temperatures are present. Another possibility is a shock in the walls of the outflow, which will also be examined further in Green et al. (in prep.).
Fig. 2. The spectrum from 55–190 μm of all spaxels added together, after removal of the continuum and rebinning to 0.5 μm resolution. Several dips or bumps (e.g., around 75 μm) are instrument artifacts. Inserts show expanded views of parts of the spectrum, with line identifications.

Fig. 3. Upper: CO line fluxes plotted versus J\text{up}. The ISO line fluxes are shown with triangles. A clear excess can be seen in the CO line fluxes from J\text{up} = 20 onwards compared to the warmest model of 750 K proposed by Giannini et al. (1999) (dashed line). Lower: CO Rotational diagram, showing two distinct populations with a break around 1500 K in energy. The blended lines are excluded from the fit and the plot. CO lines with J\text{up} larger than 31 are excluded from both plots, as these lines are detected only in the central spaxel.

4. Conclusions

We have found that the continuum models that fit the data of DK Cha are consistent with the interpretation that it is a transitional object between a stage I and stage II, with nearly equal masses in the envelope and disk and a nearly face-on geometry. The full PACS SED mode observations reveal an extremely rich spectrum of over 50 ionic, atomic, and molecular lines. With additional improvements to the spectral response function, we will be able to identify additional gas, ice, and dust features in the spectrum. The full range scan/SED mode will be able to probe many aspects of a protostellar object, from the ambient envelope to gas excited by ultraviolet radiation and by shocks.

Acknowledgements. Support for this work, part of the Herschel Open Time Key Project Program, was provided by NASA through an award issued by the Jet Propulsion Laboratory, California Institute of Technology. The authors would like to thank Bart VandenBussche and Alessandra Contursi for help with the data reduction, and David Ardila for his help in scheduling the observations prior to the ESAC SDP workshop.
