### Origin of the hot gas in low-mass protostars

**Herschel-PACS spectroscopy of HH 46**

(Affiliations are available in the online edition)

Received 31 March 2010 / Accepted 10 May 2010

### ABSTRACT

**Aims.** “Water In Star-forming regions with Herschel” (WISH) is a Herschel key programme aimed at understanding the physical and chemical structure of young stellar objects (YSOs) with a focus on water and related species.

**Methods.** The low-mass protostar HH 46 was observed with the Photodetector Array Camera and Spectrometer (PACS) on the Herschel Space Observatory to measure emission in H2O, CO, OH, [O I], and [C II] lines located between 63 and 186 μm. The excitation and spatial distribution of emission can disentangle the different heating mechanisms of YSOs, with better spatial resolution and sensitivity than previously possible.

**Results.** Far-IR line emission is detected at the position of the protostar and along the outflow axis. The OH emission is concentrated at the central position, CO emission is bright at the central position and along the outflow, and H2O emission is concentrated in the outflow. In addition, [O I] emission is seen in low-velocity gas, assumed to be related to the envelope, and is also seen shifted up to 170 km s\(^{-1}\) in both the red- and blue-shifted jets. Envelope models are constructed based on previous observational constraints. They indicate that passive heating of a spherical envelope by the protostellar luminosity cannot explain the high-excitation molecular gas detected with PACS, including CO lines with upper levels \( \leq 500–2000 \) K. Instead, warm CO and H2O emission is probably produced in the walls of an outflow-carved cavity in the envelope, which are heated by UV photons and non-dissociative C-type shocks. The bright OH and [O I] emission is attributed to J-type shocks in dense gas close to the protostar. In the scenario described here, the combined cooling by far-IR lines within the central spatial pixel is estimated to be \( 2 \times 10^{-5} \ L_\odot \), with 60–80% attributed to J- and C-type shocks produced by interactions between the jet and the envelope.

**Key words.** astrochemistry – stars: formation – ISM: molecules – ISM: jets and outflows – ISM: individual objects: HH 46

### 1. Introduction

The embedded phase of star formation is a critical period in the evolution of a young star, because it is the stage where the final mass of the star, the size and mass of the protoplanetary disk, and the initial chemical composition of the disk are determined (André et al. 2000; Visser et al. 2009; Jørgensen et al. 2009). Many physical processes occur simultaneously in the immediate surroundings of the protostar: infall in the collapsing envelope, outflows sweeping up and shocking the material, and energetic (UV and X-ray) photons heating and dissociating the gas (Spaans et al. 1995; Bachiller & Tafalla 1999; Arce et al. 2007). Because of high extinction, these processes can only be probed at far-infrared and millimetre wavelengths, but lack of observational facilities has hampered their quantification. The goal of the “Water In Star-forming regions with Herschel” (WISH) key programme is to use H2O, CO and related species to determine the physical and chemical characteristics of young stellar objects (YSOs) as functions of evolutionary stage and across a wide range of luminosities and masses (see also Nisini et al. 2010; Fich et al. 2010).

One of the many surprises of ISO was the detection of highly excited CO and H2O lines towards low-mass YSOs with the long-wavelength spectrometer (LWS, e.g., Giannini et al. 1999; Ceccarelli et al. 1999; Nisini et al. 2002). The origin of this hot gas (~500–2000 K) has been heavily debated, with two main explanations put forward: (i) shocks extending over a large area (arcmin scale); and (ii) the envelope heated by the protostellar luminosity on scales of 2–20″. The ISO-LWS data and subsequent modelling could not distinguish between these scenarios given the large beam of ~80″. The smaller aperture of Herschel-PACS allows imaging of these lines at 9′′4, sufficient to separate...
the on- and off-source emission. Moreover, its higher sensitivity and higher spectral resolution allow detection of weaker lines.

This letter presents science demonstration phase observations of HH 46, an isolated low-mass protostar ($L_{bol} \approx 16 L_{\odot}$, $D \approx 450$ pc) located in a dense core with a prominent outflow extending out to ~2$'$.

It has been imaged with the Spitzer Space Telescope (Velusamy et al. 2007) and ground-based sub-millimetre telescopes (van Kempen et al. 2009, and references therein). Because of its well-defined geometry, HH 46 provides an ideal testbed for separating the different physical components contributing to the observed emission and for benchmarking new models of YSOs that can be used for other sources.

2. Observations and results

HH 46 was observed on 26 October 2009 with Herschel (Pilbratt et al. 2010) using PACS (Poglitsch et al. 2010) in pointed line-scan spectroscopy mode (obsid 1342186315 and 1342186316). PACS is a 5 $\times$ 5 array of 9$'$x 9$'$x 4 spatial pixels (spaxels) that cover the 53–210 $\mu$m wavelength range with a spectral resolution ranging from 1000 to 4000 (the latter only at ~63 $\mu$m) in spectroscopy mode. In one exposure, a wavelength segment is observed in the first order (105–210 $\mu$m) or third order (53–72 $\mu$m). The PACS spectrum of HH 46 covers 27 segments obtained in 15 separate integrations of 350 s each. Two different nod positions, located 6$'$ in opposite directions from the target, were used to correct for telescopic background.

Data were reduced with HIPE v2.4.0. The relative spectral response function within each band was determined from ground calibration prior to launch. The absolute wavelength scale is accurately to 30–50 km s$^{-1}$, depending on the position of the emission peak in the cross-dispersion axis within the slit. The absolute flux calibration below and above 100 $\mu$m was separately determined from in-flight observations of (point) calibration sources. The uncertainty in absolute and relative fluxes is estimated to be 50%, based on a comparison with the ISO-LWS continuum data from Nisini et al. (2002).

Emission is detected in lines of H$_2$O, CO, OH, OI, and C II (Table 1, Fig. 1). Nisini et al. (2002) detected only the [OI] 63 and 145 $\mu$m and [CII] 158 $\mu$m lines with ISO. The typical 3$\sigma$ sensitivity is ~10$^{-11}$ W m$^{-2}$ to an unresolved emission line and unlike the [OI] line, the molecular lines are all unresolved. The PACS emission in most lines and in the continuum is strongly peaked at the central position. Emission in many lines is also seen along the red and blue outflow lobes including bright emission in the spaxel centred 11$''$ SW of the source. Tables 1 and 2 (the latter available online) list the line fluxes at the source position, in the red and blue outflows, and in the total field-of-view. The fluxes in the central spaxel were corrected for the point-source PSF. Fluxes for the outflows were measured over the spaxels indicated in Fig. 1 and corrected for the leaking of light from the central spaxel into adjacent spaxels.

Nine lines of water are detected in the central spaxel with $E_{sa}/k_B$ ranging from 114 to 320 K. Most H$_2$O emission lines peak at the location of strong outflow emission 11$''$ SW (Table 2). Emission in CO lines ranging from $J_a = 14$ to 30 ($E_{sa}/k_B = 580–2600$ K) is seen in both the central spaxel and in the outflows (Tables 1 and 2; Fig. 2). Strong OH emission is detected in the four doublets at 79, 84, 119, and 163 $\mu$m, arising from levels up to 290 K above the ground state. The OH emission is strongly concentrated on-source, although emission in the 119 $\mu$m doublet is also seen in the direction of the red outflow.

---

**Fig. 1.** The [OI] 63 $\mu$m, CO 16–17, 15–16 $\mu$m, H$_2$O 2–1, 13–14 $\mu$m lines and the OH doublet at 84 $\mu$m (possibly blended with a small contribution from CO 31–30), at the central position (O8$^b$25$^a$43$^a$9; -51$^i$00'36$''$; J2000) and integrated over the red- and blue-shifted outflow lobes. The vertical lines show the velocity of [OI] emission at rest (dashed) and in the blue- and red-shifted jets (dotted). The Spitzer image of HH 46 (Velusamy et al. 2007) is shown with the PACS footprint and ISO beam overlaid. The spaxels covering the red- and blue-shifted lobes are indicated with coloured boxes. The central spaxel is shown in black.

**Table 1.** Line fluxes observed towards HH 46 with PACS.

**Notes.**

* (a) Flux in the central spaxel, in 10$^{-18}$ W m$^{-2}$, Values with colons indicate weak detections or detections in only one nod. (b) Lines blended. (c) 3$\sigma$ upper limit. (d) Blue-shifted [OI] component at $v = -170$ km s$^{-1}$, (e) Doublet transitions.

Emission in the [OI] 63 $\mu$m and [CII] 158 $\mu$m lines is found to be extended over most of the PACS field-of-view. The total flux in these two lines is about 1.5 and 7 times weaker, respectively, in the PACS field (50$''$ x 50$''$) than it was in the ISO-LWS beam (~80$''$). Thus, most of the [CII] and some of the [OI] emission must be located within the ISO field but beyond that of PACS or in a relatively smooth background extending out to the PACS nod positions.

The high PACS spectral resolution at 63 $\mu$m of ~100 km s$^{-1}$ allows the [OI] 63 $\mu$m emission to be resolved into three velocity components (see Fig. 1). In addition to the main component around $v = 0$ km s$^{-1}$ peaking on-source, strong red- and
blue-shifted \([\text{O} \text{i}]\) 63 \(\mu\)m emission is detected at 110 and 
\(-170\) km s\(^{-1}\), respectively, in several spaxels to the SW and NE
of the central source. Velocities are consistent with the jet veloc-
ities measured in near-IR and optical lines (e.g., Nishikawa et al.
2008; Garcia Lopez et al. 2010).

3. Analysis

Previous observations of HH 46 have revealed many proper-
ties of the circumstellar environment including the dense cen-
trally concentrated envelope containing the protostar HH 46 IRS,
the presence of warm gas along the outflow walls heated by
UV radiation (van Kempen et al. 2009), the shape and size of
the outflow cavities, and the presence of jets and shocks (e.g.,
Velusamy et al. 2007). The temperature (10–250 K) and den-
sity (\(10^{4}–10^{6}\) cm\(^{-3}\)) structure of the passively heated envelope
have been determined in spherical symmetry by fitting dust ra-
diative transfer models to the spectral energy distribution of
the source and the spatial extent of the continuum emission.
Using these properties, a set of existing models (Kristensen et al.
2008) is rerun with the new 3D non-LTE radiative transfer code
LIME (Brinch & Hogerheijde, in prep.) to obtain fluxes of the
higher-J CO lines. The second component, the UV-heated gas in
the outflow cavity walls (Spaans et al. 1995; van Kempen et al.
2009), is modelled according to the method of Bruderer et al.
(2009). The basis is the same spherical envelope profile, but a
65 000 AU \(\times\) 13 000 AU ellipsoidal cavity is now carved out
at an inclination of 53° (Velusamy et al. 2007; Nishikawa et al.
2008). The only free parameter in this scenario is the protostellar
FUV luminosity, which is assumed to be 0.1 \(L_{\odot}\) (i.e., \(G_{0} \approx 10^{4}\)
at 100 AU with respect to the interstellar radiation field). The
gas temperature in the cavity walls is parameterised from the
grid of PDR models by Kaufman et al. (1999) and is typically a
few hundred K; the dust temperature and density profiles are un-
changed from the spherical model. More details will be reported
by Visser et al. (in prep.), who will explore a wider parameter
space to assess the viability of other scenarios.

Small-scale shocks created by the outflow along the cavity
walls are the third component considered for the molecular emis-
ion. Their temperature is typically a few thousand K. The shock
emission is computed by tiling a number of 1D C-type shock models
along the 2D cavity shape (Kristensen et al. 2008), taking the
width of each shock to be the region over which the consid-
ered species contributes significantly to the cooling in 1D shock
models. This can effectively be considered as an estimate of the
beam filling factor. For each density in the range \(10^{4}–10^{5}\) cm\(^{-3}\),
the emission is computed using the results from Kaufman &
Neufeld (1996). The only free parameter in this model is the
shock velocity, which is assumed constant along the walls. For
the case of CO, a velocity of 20 km s\(^{-1}\) reproduces the observ-
ations, and this velocity is adopted for the other species as well.

3.1. CO

The PACS data (Sect. 2) are complemented by spectrally re-
solved \(J_{u} \leq 7\) lines (\(E_{u}/k_{B} \leq 155\) K) detected with APEX
(\(\Delta v \approx 10\) km s\(^{-1}\), van Kempen et al. 2009). The \(CO/\text{H}_{2}\)
 abundance ratio in the model is taken to be \(1.6 \times 10^{-4}\) above 20 K
and below \(10^{5}\) cm\(^{-3}\). In colder regions, freeze-out lowers the
CO abundance by a factor of 100.

The model spectra are convolved with the PACS beam at the
relevant wavelength and extracted from a 9′′ square spaxel at the
centre. Figure 2 shows the observations, together with the
model predictions from the passive envelope, the UV-heated cavity
walls, and the small-scale C-type shocks. Individually, each
component only fits part of the data, but together they reproduce
the observations over the entire range of rotational levels from
\(J_{u} \approx 2–32\). The results confirm the plausibility of the scenario
without excluding other solutions not investigated here.

3.2. \(\text{H}_{2}\text{O}\)

The passive envelope underproduces the observed \(\text{H}_{2}\text{O}\) fluxes by
two orders of magnitude. Predicting fluxes from any 2D model
such as the UV-heated cavity walls is uncertain by an order of
magnitude due to challenges of radiative transfer modelling
of \(\text{H}_{2}\text{O}\). Within these uncertainties, both the UV-heated cavity
model and the C-type shock model are able to reproduce the ob-
servations independently. The former requires an \(\text{H}_{2}\text{O}\) gas abun-
dance of only \(\sim 10^{-7}\) in the cavity walls and \(\sim 10^{-8}\) in the rest
of the envelope, as expected from chemical models including
photodissociation and freeze-out. The C-type shock component
matches the observations if the abundances from Kaufman &
Neufeld (1996) are scaled down to \(\sim 7 \times 10^{-5}\). This could be
accomplished by photodissociation of \(\text{H}_{2}\text{O}\) in the shocked gas.
More detailed modelling, including spatially extended emission
and a comparison with spectrally resolved line profiles observed
with HIFI, is needed to distinguish these scenarios.

3.3. \([\text{O} \text{i}])

Within the passively heated envelope and cavity walls, the 2D
models presented above yield an \([\text{O} \text{i}]\) 63 \(\mu\)m emission line that
is narrow (3–4 km s\(^{-1}\)), optically thick, and weaker than the observed flux by more than three orders of magnitude, for an O\(1\) abundance of \(10^{-6}\). C-type shocks fail to reproduce the observations by seven orders of magnitude, and are still insufficient even if all H\(_2O\) is dissociated into O\(1\). The observed emission is, however, reproduced in a dissociative J-type shock (Neufeld \\& Dalgarno 1989). Thus, for the central spaxel, where bright emission is seen at the systemic velocity, [O\(1\)] may trace the impact of the high-velocity jet on the densest parts of the envelope (\(v_{\text{shock}} > 10^{12} \text{ cm}^{-3}\)), causing rapid deceleration from \(v > \) 200 km s\(^{-1}\) while cooling the gas through [O\(1\)] emission. The observed [O\(1\)] 63/145 \(\mu\)m line ratio is \(\sim 16\) in the central spaxel. Shock models predict ratios of 14–20, where the lower ratio applies to higher densities (\(10^{6}\) cm\(^{-3}\), Neufeld \\& Dalgarno 1989). The high-[O\(1\)] emission observed in both the central and adjacent spaxels can be produced in fast, dissociative shocks in the much lower density jet itself.

3.4. OH

The OH line ratios were modelled separately for a single-component slab model using an escape probability code with absorbing and emitting dust continuum (similar to Bruderer et al. 2010). Comparison with the observed line ratios and intensities shows that the OH lines likely originate in a high-density and high-temperature region (\(n_{\text{OH}} \sim 10^{17} \text{ cm}^{-3}\), \(T_{\text{gas}} > 800\) K). Along with the lack of extended emission, this rules out an origin in the photon-heated cavity walls and C-type shocks along the cavity walls. An OH column density of \(\sim 10^{16} \text{ cm}^{-2}\) gives the best fit to the observations along with a physical size of the OH emitting region of \(0.5\) \((\sim 250\) AU). Other solutions are possible and will be discussed in a forthcoming paper (Wampfler et al., in prep.).

The models indicate that better fits are obtained for temperatures higher than what can be accounted for in a passive envelope model. The major competing coolant to O\(1\) in a fast, dissociative shock is OH (Neufeld \\& Dalgarno 1989), and it is therefore likely that some of the OH emission is caused by the jet shock impinging on the inner, dense envelope. Further modelling, including combinations of C- and J-type shocks (Snell et al. 2005), will be explored to constrain the origin of the OH emission.

3.5. Origin of hot gas

Table 3 summarizes the assignment of the various species to the different proposed physical components. It also includes the total far-IR cooling through H\(_2O\), CO, OH, and [O\(1\)] lines in the central spaxel. Within our scenario, cooling by CO takes place almost equally through the UV-heated cavity walls and the small-scale C-type shocks. The observed H\(_2O\) emission can be accounted for either by UV heating of the cavity walls or by C-type shocks, or a combination. It is impossible to distinguish between the two scenarios at present; however, the total cooling is \(5 \times 10^{-3}\) \(L_{\odot}\) in both cases using the above models to account for the non-observed line emission.

Cooling through [O\(1\)] emission takes place on very small spatial scales, probably related directly to the jet impinging on the envelope walls. OH emission likely arises in the same dissociative shock. The OH cooling in observed lines is \(2.4 \times 10^{-3}\) \(L_{\odot}\), but the total OH cooling can be an order of magnitude higher if an excitation temperature of 200 K is used to account for non-observed lines. Thus, the total cooling caused by J- and C-type shocks is at least \(1.5 \times 10^{-2}\) \(L_{\odot}\) or 60% of the total far-IR line cooling. The two other components (passive and UV) are responsible for the remaining 40% of the total cooling. ISO-LWS found typical far-IR line cooling rates of \(1–5 \times 10^{-2}\) \(L_{\odot}\) (Nisini et al. 2002), comparable to what is observed here. The total cooling of the entire HH 46 system is higher, since only the central spaxel is considered here.

In summary, the Herschel-PACS data allow for disentangling and quantifying the energetic processes occurring in deeply embedded protostars. The models indicate, that of the two scenarios previously proposed based on ISO-LWS data, shocks are more important than the passively heated envelope in powering the far-infrared lines. Another component, the UV-heated cavity walls, also plays an important role in producing line emission. HIFI observations resolving emission lines are planned to test the proposed scenario in the framework of the WISH key programme.

Acknowledgements. This work is made possible thanks to the HIFI guaranteed time programme and the PACS instrument builders. We thank Javier Gracia Carpio, Jeroen Bouwman, Bruno Merín, and Bart VandenBussche for help with the PACS data reduction and many funding agencies for financial support. We also thank the referee for comments that improved this paper.

</table>

Notes.\(^{(a)}\) Fluxes are measured from Gaussian fits. Lines marked with a colon are only weakly detected. Listed uncertainties are 68% confidence intervals, upper limits are 95% confidence intervals. The uncertainties do not include the 50% error margin in the relative spectral response function.\(^{(b)}\) The total flux is less than the combined flux from the central spaxel, the red outflow and the blue outflow. This is a result of higher noise in the spectrum summed over all spaxels, leading to a different fit and PSF over-correction.\(^{(c)}\) The CO 23–22 and H$_2$O 4$1_{1}$–3$0_{3}$ lines at 113.5 $\mu$m are blended.\(^{(d)}\) The CO 31–30 and OH 3/2,7/2–3/2,5/2 lines at 84.4 $\mu$m are blended.\(^{(e)}\) Doublet transitions.\(^{(f)}\) Blue- and red-shifted components of the [OI] 63.2 $\mu$m line. The blue component is not detected in the spaxels covering the red outflow, and vice versa. Furthermore, the red component is not detected in the central spaxel.
