ABSTRACT

We obtained Herschel PACS and SPIRE images of the thermal emission of the debris disk around the A5V star β Pic. The disk is well resolved in the PACS filters at 70, 100, and 160 μm. The surface brightness profiles between 70 and 160 μm show no significant asymmetries along the disk, and are compatible with 90% of the emission between 70 and 160 μm originating in a region closer than 200 AU to the star. Although only marginally resolving the debris disk, the maps obtained in the SPIRE 250–500 μm filters provide full disk photometry, completing the SED over a few octaves in wavelength that had been previously inaccessible. The small far-infrared spectral index (β = 0.34) indicates that the grain size distribution in the inner disk (<200 AU) is inconsistent with a local collisional equilibrium. The size distribution is either modified by non-equilibrium effects, or exhibits a wavy pattern, caused by an under-abundance of impactors which have been removed by radiation pressure.

Key words. stars: early-type – planetary systems – circumstellar matter – stars: individual: β Pic

1. Introduction

The β Pic disk, discovered by IRAS (Aumann et al. 1984), was the first debris disk to be directly imaged in scattered light (Smith & Terrile 1984). It is seen close to edge-on and extends in the optical out to 95″, corresponding to 1800 AU (Larwood & Kalas 2001).

β Pic (A5V) is one of the closest (19.44 ± 0.05 pc, van Leeuwen 2007) and youngest debris disks. The estimated age (12 Myr, Zuckerman et al. 2001) significantly exceeds typical timescales for the survival of pristine circumstellar dust grains (e.g., Fedele et al. 2010), hence continuous replenishment of the dust, presumably through collisions of planetesimals, is needed. The closeness of the object ensures that it can also be spatially resolved at long wavelengths: Holland et al. (1998) resolved the disk at 850 μm and Liseau et al. (2003) at 1200 μm.

Optical and near-infrared observations of the inner part (<100 AU) of the disk yield evidence of asymmetries such as warps and density contrasts, which may relate to the presence of planetesimals (Kalas & Jewitt 1995; Pantin et al. 1997; Mouillet et al. 1997; Heap et al. 2000; Telesco et al. 2005). Lagrange et al. (2009) imaged a possible companion at a projected distance of 8 AU from the star.

Images of β Pic in scattered stellar light directly detect small grains and indirectly larger grains that produce the smaller ones through collisions. The grain-size distribution can be quantitatively constrained from the spectral energy distribution (SED) of the disk, in the infrared and (sub)mm domains. The spectral index of the SED at the longest wavelengths (Liseau et al. 2003; Nilsson et al. 2009) is inferred to be fairly low, which according to modeling (Draine 2006; Natta et al. 2007; Ricci et al. 2010) can be interpreted as a deficit of small grains.

In this paper, we present far-infrared imaging of the β Pic debris disk in six Herschel photometric bands between 70 and 500 μm. These bands cover for the first time the long-wavelength side of the peak in the thermal emission of the disk, and the large aperture of the telescope enables us to resolve the disk at far-IR wavelengths for the first time. With these data, we measure the surface brightness profiles of the disk and readdress the issue of the grain-size distribution in the inner 200 AU.

2. Observations and data reduction

We obtained maps of β Pic with the PACS and SPIRE instruments of Herschel (Pilbratt et al. 2010). The in-orbit performance, scientific capabilities, calibration methods, and accuracy are outlined by Poglitsch et al. (2010) for the PACS instrument and by Griffin et al. (2010) and Swinyard et al. (2010) for the SPIRE instrument. The observations were carried out during the science demonstration phase as proposed in the “Stellar Disk Evolution” guaranteed time proposal (PI G. Olofsson). Table 1 gives a summary of the observations. The deep PACS observation at 70 μm and 160 μm is a standard PACS photometer.
In Fig. 1, we show the maps obtained in the three PACS filters (70, 100, and 160 μm) and the three SPIRE filters (250, 350, and 500 μm). The PACS PSFs, rotated to match the position angle of the telescope at the time of the β Pic observations are depicted in the upper right corner of the images. The SPIRE PSFs are depicted in Fig. 6. All images are scaled linearly, contour lines are in steps of 10% of the peak flux. The surface brightness unit is Jy arcsec⁻². The white circle shows the beam FWHM. The position of the flux peaks observed at 850, 870, and 1200 μm by Holland et al. (1998), Nilsson et al. (2009), and Liseau et al. (2003) are indicated with H, N, and L.

The data processing is described in Appendix. The absolute flux calibration accuracy of the resulting PACS maps is better than 10% at 70 and 100 μm, and 20% at 160 μm (Poglitsch et al. 2010). The flux calibration accuracy of the resulting PACS maps is better than 15% (Swinyard et al. 2010). The 1σ noise levels of the maps are listed in Table 2.

3. Analysis

In Fig. 1, we show the maps obtained in the three PACS filters (70, 100, and 160 μm) and the three SPIRE filters (250, 350, and 500 μm). We also compare the point spread functions (PSFs) measured on the asteroid Vesta using the same satellite scan speed, processed as the β Pic maps and rotated to align with the telescope pupil orientation on the sky during the β Pic observations as listed in online Table 1.

These images show a clearly resolved disk from 70–160 μm. Each map was fitted using a 2D Gaussian function. Within the 2°“Herschel” pointing accuracy, the Gaussian center matches the star’s optical position. The fitted position angles, listed in Table 2, agree with the optical disk position angle of 30.8° reported by Kalas & Jewitt (1995). Cross-sections orthogonal to the disk position angle in the NW to SE direction show no significant broadening compared to the PSF. The disk is not resolved in the vertical direction. The feature towards the NW, visible in the 70–160 μm images, is produced by the three-lobed PACS PSF.

In Fig. 3, we present the surface brightness profiles along the disk position angle. We compare them with the cross-sections aligned in the same direction through the PSFs. At 250 and 350 μm, the disk is marginally resolved. At 500 μm, the β Pic profile shows no significant departure from the PSF profile, with the exception of a cold blob in the southwest. As can be seen in Fig. 1, the location of this feature in the 250–500 μm maps coincides with the flux peaks seen at 850 and 870 μm by Holland et al. (1998) and Nilsson et al. (2009), respectively. However, the 100 arcmin² region around β Pic (depicted in online Fig. 2) shows more than 50 background sources comparable to this feature in the 250 μm map. The feature is therefore probably a background source.
30.8 μm detection limit in the Fig. 4.

Gaussian to match the spatial resolution of the 160 μm filters. The profiles were convolved with a Gaussian to match the spatial resolution at 160 μm. Profiles were convolved with a Gaussian to match the spatial resolution. The wiggles in the 160 μm profiles defer significantly from that of the 160 μm PSF profile. The shape of these convolved PSF profiles are shown for the PSF maps.

The comparison of the surface brightness profiles in the three PACS filters in Fig. 4 shows the same brightness profile along the disk in NE direction following the 30.8 μm image. The same convolution was applied to the 70 μm PSF profile. Within these uncertainties, there is no evidence of a wavelength dependent surface brightness. This indicates that the grains producing the emission at 70, 100, and 160 μm are confined to the same locus in the disk. At 70 μm, the broadening of the profile with respect to the PSF indicates that 90% of the emission originates in a region within 11″ or 200 AU of the star.

4. The far-infrared SED and grain size

We integrated the surface brightness maps over a 60″ radius circular aperture. Background subtraction was based on a rectangular region, selected close enough to the object to be within the map region with the same coverage as the center of the map. For the background outlier rejection, the DAOphot algorithm in the HIPE aperture photometry task was used. The aperture photometry obtained provides a good measure of the flux density of the integrated disk. The contribution of the stellar photosphere at these wavelengths is negligible. The error is dominated by the present uncertainties in the absolute flux calibration of both instruments. The full disk flux densities are listed in Table 2.

Figure 5 shows the new PACS and SPIRE photometry, and selected infrared and (sub-)mm flux densities from the literature. Because the disk is optically thin at these wavelengths, the wavelength dependence of the emission directly probes the dust grains, and, in particular, their size distribution. We overplot two modified Rayleigh-Jeans laws (\( F_\nu \propto \nu^{q-3} \)), normalized to the 160 μm datum. The spectral index \( \beta \) indicates the mean dust opacity \( \kappa \propto \nu^q \). An index \( \beta = 0 \) corresponds to a black body with a \( \kappa \) independent of wavelength λ, indicating grains that are much larger than \( \lambda/2\pi \). Interstellar grains, which have a size distribution \( F(a) \propto a^{-q} \) with \( q = 3.5 \) and an upper size limit of \( a_{\text{max}} \sim 0.3 \) μm, are characterized by \( \beta = 1.8 \pm 0.2 \) (Draine 2006). In protoplanetary disks, \( \beta \)-values from 1.5 down to 0 are found, depending on the disk geometry (Acke et al. 2004). An error-weighted least squares fit of a Rayleigh-Jeans law to the βPic photometry at wavelengths beyond 160 μm yields \( \beta = 0.34 \pm 0.07 \). Nilsson et al. (2009) obtained \( \beta = 0.67 \) from a \( \beta \)-corrected black-body fit to the full disk SED, including mid-infrared photometry. The difference between both results should not be over-interpreted since both approaches are sensitive in different ways to simplifying assumptions about the temperature and size distribution within the disk. In any case, both results consistently show a value below 0.7. Ricci et al. (2010) demonstrate that such a low value cannot be explained with a \( q = 3.5 \) power law. This is a surprise insofar as the latter value is the expected result for a population of bodies in a standard steady-state collisional cascade (Dohmanyi 1969).
The infrared to mm SED of β Pic. The PACS (70–160 μm), and the SPIRE (250–500 μm) fluxes were integrated over a 60° radius aperture. IRAS flux densities are from the IRAS Point Source Catalog. The 850 μm SCUBA datum (Holland et al. 1998) and the 1200 μm SIMBA datum (Liseau et al. 2003) are integrated over a 40° radius aperture. Overplotted is a Rayleigh-Jeans extrapolation of the 160 μm flux density with a spectral index $q = 3.4$. The stellar photosphere is a Kurucz model for $T_{\text{eff}} = 9000$ K; log($g$) = 3.9 scaled to the 2MASS photometry $K_s = 3.52$.

The grain size distribution in β Pic must be flatter than the $q = 3.5$ power law, meaning that the fraction of small particles must be lower. Radiation pressure can push the smallest grains (with $F_{\text{rad}}/F_{\text{grav}} > 0.5$) onto hyperbolic orbits, hence reduce the time these particles spend in the inner part of the disk, which can decrease their volume density by two orders of magnitude (Krivov et al. 2000). The disk cannot be fully cleared of small particles, since it has been seen in scattered light out to 1800 AU. The scattering grains are probably the (sub-)μm grains that are blown out of the inner disk, where the collisions take place. However, this effect only reduces the densities for grains of size below a few micrometers, and even fully removing these grains would not change the β value observed.

The small value of $\beta$ can be interpreted in a number of ways. The grain size distribution can exhibit a wavy pattern, caused by the absence of impactors small enough to be efficiently blown out of the disk by radiation pressure. This causes an over-abundance of the grains that are just bound, which means there are more impactors for the next larger size population. The reduction of this population causes an over-abundance of a following size population and so on (Krivov et al. 2006). The wavy size distribution can lead to small values of $\beta$ when measured in the FIR (Thébault & Augereau 2007). If the wavy structure were as strong as found in this paper for normal and weak material properties, it would be consistent with the small $\beta$ value we have measured. However, the strength and phase of the wavy pattern in the size distribution depend on both the grain structure and the eccentricity of the dust orbits in the disk.

Alternative explanations of the small value of $\beta$ cannot be excluded. There are indications that the grains produced in the deep impact experiment followed a flatter power law with $q \approx 3.1$ (Jorda et al. 2007). Laboratory experiments illustrate that fragments produced in collisions of porous aggregates can follow much flatter slopes ($q = 1.2$, Güttler et al. 2010), demonstrating that the porosity of the colliding grains should not be disregarded.

Additional dynamical models should be developed to quantitatively describe the small $\beta$ observed in β Pic.

5. Conclusions

We have presented images of the β Pic debris disk in six photometric bands between 70 and 500 μm using the PACS and SPIRE instruments. We resolve the disk at 70, 100, 160, and 250 μm. The images at 70–160 μm show no evidence of asymmetries in the far-infrared surface brightness along the disk of β Pic. The observed profiles are compatible with 90% of the emission originating in a region within a radius of 200 AU from the star. The disk-integrated photometry in the six Herschel filters provides a far infrared SED with small spectral index $\beta = 0.34$, which is indicative of a grain size distribution that is inconsistent with a local collisional equilibrium. The size distribution is modified by either non-equilibrium effects, or exhibits a wavy pattern, caused by the under-abundance of impactors that are small enough to be removed by radiation pressure.

Appendix A: Data reduction

The PACS data were processed in the Herschel interactive analysis environment HIPE (v3.0), applying the standard pipeline steps. The flux conversion was done using version 5 of the response calibration. Signal glitches due to cosmic ray impacts were masked out in two steps. First the PACS photMMTDeglitching task in HIPE was applied on the detector timeline. Then a first coarse map was projected, which is then used as a reference for the second level deglitching HIPE task IIandLevelDeglitch. In the detector time series we masked the region around the source prior to applying a high-pass filter to remove the low frequency drifts. The scale of the high pass filter was taken to be half the length of an individual scan leg on the sky, i.e. 3.7’. The detector time series signals were then summed up into a map using the PACS photProject task. The pixel scale for the 70 and 100 μm maps was set to 1″, while the scale for the 160 μm map was 2″. For the deep map in the 70 and 160 μm filter we combined the two detector time series and projected these together.

The SPIRE data were also reduced using HIPE and maps were obtained via the default naiveMapper task. The SPIRE observation consists of several repetitions of a map observation of the same area. As a result it was possible to project the data with a pixel size of 4, 6, and 9″ while still maintaining complete sampling across the source.
