LETTER TO THE EDITOR

**Herschel observations of the hydroxyl radical (OH) in young stellar objects**

(Affiliations are available on page 5 of the online edition)

Received 31 May 2010 / Accepted 12 July 2010

**ABSTRACT**

* Aims. “Water In Star-forming regions with Herschel” (WISH) is a *Herschel* key program investigating the water chemistry in young stellar objects (YSOs) during protostellar evolution. Hydroxyl (OH) is one of the reactants in the chemical network most closely linked to the formation and destruction of H₂O. High-temperature (T ≈ 250 K) chemistry connects OH and H₂O through the OH + H₂ ⇄ H₂O + H reactions. Formation of H₂O from OH is efficient in the high-temperature regime found in shocks and the innermost part of protostellar envelopes. Moreover, in the presence of UV photons, OH can be produced from the photo-dissociation of H₂O through H₂O ⇔ H₂O + γUV ⇒ OH + H.

* Methods. High-resolution spectroscopy of the 163.12 μm triplet of OH towards HH 46 and NGC 1333 IRAS 2A was carried out with the Heterodyne Instrument for the Far Infrared (HIFI) on board the *Herschel* Space Observatory. The low- and intermediate-mass protostars HH 46, TMR 1, IRAS 15398-3359, DK Cha, NGC 7129 FIRS 2, and NGC 1333 IRAS 2A were observed with the Photodetector Array Camera and Spectrometer (PACS) on *Herschel* in four transitions of OH and two [O i] lines.

* Results. The OH transitions at 79, 84, 119, and 163 μm were detected with PACS towards the class I YSO HH 46, as well as the intermediate-mass and class I Herbig Ae sources. No OH emission was detected from the class 0 YSO NGC 1333 IRAS 2A, though the 119 μm was detected in absorption. With HIFI, the 163.12 μm was not detected from HH 46 and only tentatively detected from NGC 1333 IRAS 2A. The combination of the PACS and HIFI results for HH 46 constrains the line width (FWHM ∼ 11 km s⁻¹) and indicates that the OH emission likely originates from shocked gas. This scenario is supported by trends of the OH flux increasing with the [O i] flux and the bolometric luminosity, as found in our sample. Similar OH line ratios for most sources suggest that OH has comparable excitation temperatures despite the different physical properties of the sources.

* Key words. astrochemistry – stars: formation – ISM: molecules – ISM: jets and outflows – ISM: individual objects: HH 46

1. Introduction

The hydroxyl radical (OH) is a cornerstone species of the oxygen chemistry in dense clouds and is particularly important in the chemical reaction network of water. H₂O and OH are closely linked through the OH + H₂ ⇄ H₂O + H reactions. The formation of H₂O from OH is efficient at the high temperatures found in shocks or in the innermost parts of circumstellar envelopes (Kauffman & Neufeld 1996, Charnley 1997). Below about 250 K, standard gas-phase chemistry applies, in which H₂O is formed and destroyed through ion-molecule reactions. The OH emission is closely related to the OH + H₂ ⇄ H₂O + H reactions. The OH transitions at both higher angular and spectral resolution and at different physical properties of the sources.

The observation of far-infrared (FIR) rotational OH lines by ground based facilities is severely limited by the Earth’s atmosphere. Previous studies of OH FIR emission with the ISO showed that OH is one of the major molecular coolants in star-forming regions (e.g. Giannini et al. 2001). However, with a large beam of 80", ISO was unable to resolve the central source from the outflows, preventing an assessment of the origin of the OH emission. Interpretation of the ISO OH measurements thus relied mostly on the assumption that the OH emission arises from gas with the same temperature and density as the high-J CO emission (e.g. Nisini et al. 1999, Ceccarelli et al. 1998). The *Herschel* Space Observatory permits observations of OH FIR transitions at both higher angular and spectral resolution and at higher sensitivity than ISO. Observations of H₂O, OH and related species towards a large set of young stellar objects over a wide range of luminosities and masses are being carried out in the “Water In Star-forming regions with Herschel” (WISH) key program to trace the water chemistry during protostellar evolution (van Dishoeck et al. in prep). OH emission at 163.12 μm (1837.8 GHz) was detected with PACS towards the class I YSO HH 46
(van Kempen et al. 2010b), but the triplet, split by 90 MHz, could not be resolved. Based on modeling results, the OH emission was attributed to a J-type shock and not to the quiescent envelope. We carried out high-resolution spectroscopy with HIFI to test whether the detected OH emission is dominated by shock contribution by resolving the line profiles. This paper presents the HIFI observations in HH 46 as well as the class 0 object NGC 1333 IRAS 2A. New PACS observations of OH and [O I] are reported for the low-mass protostars IRAS 15398-3359, NGC 1333 IRAS 2A, and TMR 1.

2. Observations and data reduction
Because of spin-orbit interaction, the OH rotational levels are built within two ladders, \(^2\Pi_{3/2}\) and \(^2\Pi_{1/2}\) (Offer & van Dishoeck 1992). Each level is further split by J doubling and hyperfine structure. A level diagram can be found in Fig. C.1 in the appendix. We use the molecular data from the Leiden atomic and molecular database LAMDA\(^1\) (Schöier et al. 2005).

High-resolution observations of the OH triplet at 163.12 µm (1837.747, 1837.817 and 1837.837 GHz) were performed with the Heterodyne Instrument for the Far-Infrared (HIFI, de Graauw et al. 2010) on board the ESA Herschel Space Observatory (Pilbratt et al. 2010) towards HH 46 and NGC 1333 IRAS 2A. HIFI data were stitched together using the Herschel interactive processing environment (HIPE v3.0.1, Ott 2010) and further analyzed using GILDAS-CLASS\(^2\) software. We removed standing waves after the subtraction of a low-order polynomial and calibrated to \(T_{\text{mb}}\) scale using a main beam efficiency of 0.74. The H and V polarizations were combined.

HH 46, TMR 1, IRAS 15398-3359, and NGC 7129 FIRS 2 were observed with PACS (Poglitsch et al. 2010) in line spectroscopy mode around four OH doublets at 79, 84, 119, and 163 µm. The [O I] 63 and 145.5 µm lines were also observed except for TMR 1. Each segment at \(\lambda < 100 \mu m\) and \(\lambda > 100 \mu m\) covers 1 and 2\(\mu m\) at \(R \sim 3000\) and \(R \sim 1500\), respectively. In addition, DK Cha and NGC 1333 IRAS 2A were observed with PACS from 55–210 \(\mu m\) at \(R \sim 1000\) in range spectroscopy mode. Details of the PACS observations of HH 46, NGC 7129 FIRS 2, and DK Cha are described in van Kempen et al. (2010b), Fich et al. (2010), and van Kempen et al. (2010a), respectively. All spectra were reduced with HIPE v2.9. PACS spectra are recorded in a 5 \(\times\) 5 array of 9\(^\prime\)/4 square pixels (spaxels). The observations of IRAS 15398-3359, TMR 1, NGC1333 IRAS 2A, and DK Cha were mispointed sufficiently in a way that the peak of the continuum emission differs from the central spaxel.

The line and continuum emission seen by PACS is spatially extended in most cases. Spectra were extracted from the spaxels that include OH emission. The wavelength-dependent point-spread function was roughly corrected by comparing the amount of continuum emission in the summed spaxels to that in the total array. Most integrated line intensities were derived from Gaussian fits to the unresolved lines. In a few cases, the OH doublets could not be resolved and the intensities were then derived by simple integration over the spectrum. The absolute flux calibration below and above 100 \(\mu m\) was separately determined from in-flight observations of (point) calibration sources. The relative spectral response function within each band was determined from ground calibration prior to launch. The uncertainty in absolute and relative fluxes is estimated to be 30–50%. Additional details on the observations can be found in the appendix.

1 \(\text{http://www.strw.leidenuniv.nl/~moldata/}\)
2 \(\text{http://www.iram.fr/IRAMFR/GILDAS}\)

3. Results
HIFI did not detect the 163.12 \(\mu m\) OH hyperfine triplet at the level of \(T_{\text{ms}} \approx 70\) mK on \(T_{\text{mb}}\) scale for the nominal WBS resolution of about 1.1 MHz (0.163 \(km s^{-1}\)). The spectrum is presented in Fig. 1. Combining the HIFI and PACS observations constrains the line width (see Sect. 4).

PACS detected OH emission at 79, 84, 119, and 163 \(\mu m\) towards the class I sources HH 46, TMR 1 and IRAS 15398-3359 as well as the class I Herbig Ae star DK Cha and the intermediate-mass source NGC 7129 FIRS 2 (Fig. 2). An exception is the 163.40 \(\mu m\) line of HH 46, where we only have an upper limit because of the uncertain baseline towards the end of the spectral window where the line is located. The [O I] 63 \(\mu m\) and 145 \(\mu m\) lines were also detected. An overview of the results is given in Table 1. The 1\(\sigma\) errors listed in Table 1 do not include the systematic error of 30–50% from uncertainty in the calibration. Because of blending with CO(31–30), the 84.42 \(\mu m\) doublet component of OH is not listed. For the analysis, we assumed the flux to be identical to the 84.60 \(\mu m\) OH flux because all observed doublets show comparable fluxes of the components within the calibration uncertainty.

The only class 0 YSO in the sample, NGC 1333 IRAS 2A, is fundamentally different from all other sources in the sample. The OH 119 \(\mu m\) doublet is seen in absorption, with an equivalent width of about 7.5 \(km s^{-1}\) for each component. No other OH lines were detected at the noise level obtained after removal of the fringe effects. However, the upper limits are larger than the fluxes detected from the class I sources. On the other hand, the upper limit on the [O I] 63 \(\mu m\) line emission is at least a factor of four lower than the weakest [O I] 63 \(\mu m\) line found in our sample.

4. Analysis
To constrain the line width of the 163.12 \(\mu m\) OH triplet from HH 46, the HIFI non-detection is combined with the flux (22 \(\times\) 10\(^{-18}\) \(W m^{-2}\)) of the unresolved lines measured with the high-sensitivity PACS instrument. The expected integrated intensity for HIFI is \(\sim 1.1\) \(Km s^{-1}\) for the triplet in total, as calculated from the PACS observation. This value was derived for a 13\(^\prime\) beam under the assumption that the source is unresolved, because the OH emission from HH 46 appears to be centrally concentrated (van Kempen et al. 2010b). Assuming LTE ratios \((-A_{ij}\sigma)\) for the three components, the strongest transition has an integrated intensity of 0.66 \(Km s^{-1}\). An upper limit on the integrated intensity is calculated from the HIFI observation using
Dashed vertical lines indicate the OH frequencies, dotted thick. It can also be a
pared to higher excitation lines because this line, which is con-
yingly similar characteristics in terms of their OH emission: the
sources, Ser SMM1 (Larsson et al. 2002) and NGC 1333 IRAS 4
the uncertain baseline, this needs to be treated with caution.
Fig. 3 compares the OH fluxes from YSOs as measured
levels among the sources. The line ratios of different sources agree within a factor of two except when the
OH transition is involved (Fig. B.1 in the appendix) and are consistent with the results from ISO observations from the
class 0 sources NGC 1333 IRAS 4 and Ser SMM1.
Emission in the 84 μm transition, which has \( E_{\text{up}}/k_B \approx 300 \) K, indicates that OH is tracing the warm (\( T \geq 100 \) K) and dense (\( n \geq 10^3 \) cm\(^{-3}\)) gas in our sources. Modeling results show that
tions in the \( ^2\Pi_{1/2} \) ladder are mostly excited by collisions while the population of the \( ^2\Pi_{1/2} \) levels is dominated by radiative
The weak 163 μm lines and emission at 79 μm indicate that FIR pumping is less important than collisional excitation in our sources.
Figure 4 shows the trend of stronger OH emission with increasing bolometric source luminosity \( L_{\text{bol}} \) found in our source sample. We calculated the OH line luminosity \( L_{\text{OH}} \) individually for each transition and source from the observed fluxes and found indications that the differences between the sources may depend on the individual \( L_{\text{bol}} \). The correlation between \( L_{\text{OH}} \) and \( L_{\text{bol}} \) is reminiscent of that found for the CO outflow force with
Emission of di-atomic species in the lower \( |J|=1 \) – 0 ladder are mostly excited by collisions with cold gas layers lying in front of the source. The 79 μm doublet links the lowest energy states of both rotational ladders, but because of the smaller Einstein A coefficients of the cross-ladder transitions, these lines are less affected by optical depth than the
σ = 1.3 ζ \( \Delta \omega \Delta T_{\text{mb}} \) with \( \Delta \omega \) the velocity resolution, \( \Delta T_{\text{mb}} \) the expected line width and an assumed 30% calibration uncertainty. Rebinning the spectrum to a resolution of 16 MHz (2.6 km s\(^{-1}\)) yields an rms of 31 mK and would therefore allow 5σ (3σ) detections for Gaussian lines with \( \sigma = 1.3 \). For comparison, the \( FWHM \leq 4 \) km s\(^{-1}\) (\( FWHM \leq 11 \) km s\(^{-1}\)). From the non-detection we conclude that the flux observed with PACS is likely to be emitted from lines with \( FWHM \leq 11 \) km s\(^{-1}\). For comparison, the \( FWHM \) of the H2O
levels among the sources. The line ratios of different sources agree within a factor of two except when the
OH doublet is the dominant coolant, \( \sigma_{\text{OH}} \leq 10 \) km s\(^{-1}\) for the strongest component in NGC 1333 IRAS 2A, in agreement with the upper limits on OH emission in the PACS observation of the same source. Given the uncertain baseline, this needs to be treated with caution.

Notes. * Doublet not resolved. Table lists the integrated flux over both components.

\[ \delta v_{\text{FWHM}} = 1.3 \sqrt{\frac{c}{\nu}} \Delta T_{\text{mb}} \]

\[ \delta v_{\text{FWHM}} = 1.3 \sqrt{\frac{c}{\nu}} \Delta T_{\text{mb}} \]
surprisingly similar OH line ratios despite the large range of physical properties covered in this study, suggesting that OH emission might arise from gas at similar conditions in all sources. Furthermore, we find trends of correlations between OH integrated intensities and [O I] emission as well as bolometric luminosity, consistent with an origin in the wake of dissociative shocks. Given the low number of sources in the sample, confirmation from additional observations is needed. In a similar HIFI observation, OH emission was tentatively detected below the S/N level for the strongest triplet component in NGC 1333 IRAS 2A, in agreement with the upper limits on OH emission in the PACS observation of the same source. Given the uncertain baseline, this needs to be treated with caution. Further OH observations and modeling should eventually allow the determination of the OH/H$_2$O abundance ratio in shocks, which traces the UV field through its dependence on the fraction of atomic to molecular hydrogen.

Appendix A: Observational details

Table A.1 lists the coordinates, observing dates, and the observation identity numbers of our sources along with the assumed distance, the bolometric luminosity, the envelope mass and the source type. For comparison, Ser SMM1 and NGC 1333 IRAS 4 observed with ISO are included as well. For Ser SMM1, we use the average values of the fluxes presented by Larsson et al. (2002). The data for NGC 1333 IRAS 4 are taken from Giannini et al. (2001). Note that for NGC 1333 IRAS 4, we use the luminosity and mass of NGC 1333 IRAS 4A.
