Water cooling of shocks in protostellar outflows

Herschel-PACS map of L1157*

(Affiliations are available in the online edition)

Received 31 March 2010 / Accepted 23 April 2010

ABSTRACT

Context. The far-IR/sub-mm spectral mapping facility provided by the Herschel-PACS and HIFI instruments has made it possible to obtain, for the first time, images of H2O emission with a spatial resolution comparable to ground based mm/sub-mm observations.

Aims. In the framework of the Water In Star-forming regions with Herschel (WISH) key program, maps in water lines of several outflows from young stars are being obtained, to study the water production in shocks and its role in the outflow cooling. This paper reports the first results of this program, presenting a PACS map of the o-H2O 179 μm transition obtained toward the young outflow L1157.

Methods. The 179 μm transition is correlated with emission from H2 rotational lines, excited in shocks leading to a significant enhancement of the water abundance. Water emission peaks along the outflow also correlate with peaks of other shock-produced molecular species, such as SiO and NH3. A strong H2O peak is also observed at the location of the proto-star, where none of the other molecules have significant emission. The absolute 179 μm intensity and its intensity ratio to the H2O 557 GHz line previously observed with Odin indicate that the water emission originates in warm compact clumps, spatially unresolved by PACS, having a H2O abundance of the order of 10−4. This testifies that the clumps have been heated for a time long enough to allow the conversion of almost all the available gas-phase oxygen into water. The total H2O cooling is about 40% of the cooling due to H2 and 23% of the total energy released in shocks along the L1157 outflow.

Key words. stars: formation – ISM: jets and outflows – ISM: molecules

1. Introduction

Among the main coolants in molecular shocks, water is the tracer most sensitive to physical variations and the temporal evolution of protostellar outflows, thus representing a very powerful probe of their shock conditions and thermal history (e.g., Bergin et al. 1998). Water emission and excitation in shocks were studied extensively for the first time with ISO, the first space facility with spectroscopic capabilities in the mid- and far-IR. ISO surveyed the water emission in a large sample of outflows from young stellar objects (YSOs), providing a global statistical picture of the importance of water in the outflow cooling and of variations in its abundance with shock properties and ages (see e.g., Nisini 2003; van Dishoeck 2004). Following ISO, the SWAS and Odin facilities made it possible to observe the ortho-H2O fundamental line at 557 GHz, providing important constraints on the water abundance and kinematics in the cold outflow gas components (e.g., Franklin et al. 2008; Bjerkeli et al. 2009). All these facilities, however, had poor spatial resolution (i.e., greater than 80′′), which did not allow one to locate the origin of the water emission nor study variations in abundances and excitation within individual flows.

In this framework, a sample of YSO outflows will be surveyed in different water lines by the PACS and HIFI instruments onboard the Herschel satellite, as part of the key program WISH (Water In Star-forming-regions with Herschel). This paper presents the first results obtained from this survey, consisting of a PACS map of the H2O 21−10 179 μm line covering the

outflow of the protostar L1157-mm, obtained during the Herschel science demonstration phase. The 179 μm line is the transition connecting the lower two back-bone levels of ortho-H$_2$O. It is therefore one of the brightest water lines expected in collisionally excited conditions, thus representing an ideal tracer of the water distribution in shocked regions. L1157 is a well known outflow driven by a low mass class 0 object (L1157-mm, $L_{\text{bol}} \sim 8.3$ $L_\odot$, $D \approx 440$ pc, Froebrich 2005). It is considered to be the prototype of chemically active flows, given the large number of different species detected in its shocked regions (e.g., Bachiller & Perez-Gutierrez 1997). This paper is presenting the first of several observations planned for this source by the WISH team.

2. Observations

Observations were performed on 26 October 2009 with the PACS instrument (Poglitsch et al. 2010) onboard the Herschel Space Observatory (Pilbratt et al. 2010) in line spectroscopic mode, with the grating centred on the H$_2$O 2$_{12}$−1$_{01}$ line at 179.527 μm. The L1157 outflow region (of about $6' \times 2'$) was covered by 12 individual PACS raster maps, arranged along the outflow axis. Each map consists of $3 \times 3$ PACS frames acquired in steps of 40″. The instrument is a 5 × 5 pixel array providing a spatial sampling of 9.4"/pixel, while the spectral resolution at 179 μm is $R \sim 1500$ (i.e., $\sim 210$ km s$^{-1}$). The data were reduced with HIPE 2.0. Additional IDL routines were developed to construct a final integrated and continuum-subtracted line map. Flux calibrations used calibration files obtained by ground tests that remain very uncertain at the time of paper writing, especially for extended sources. To evaluate the flux uncertainty, we compared with the three measurements performed by the ISO satellite along the outflow (Giannini et al. 2001). To do that, we performed aperture photometry of the line emission in the PACS map within the 80″ ISO circular beam. The ratio of PACS to ISO fluxes ranges between 1.1 and 1.8 at the three positions: we adopt this as the uncertainty in our quantitative analysis. The typical rms noise across the map is of the order of $2 \times 10^{-2}$ erg s$^{-1}$ cm$^{-2}$ sr$^{-1}$.

3. Results and comparison with other tracers

Figure 1 presents the PACS map of the 179 μm line emission. In the same figure, the H$_2$O map is overlaid with contours of the emission from the H$_2$O 0−0 S(1) (Neufeld et al. 2009), CO 2−1 and SiO 3−2 (Bachiller et al. 2001) transitions. The water map exhibits several emission peaks corresponding to the positions of previously known shocked knots, labelled as B0-B1-B2 for the south east blue-shifted lobe, and R0-R-R2 for the north west red-shifted lobe, following the nomenclature of Bachiller et al. (2001). These emission knots represent the actual working surfaces of a precessing and pulsed jet and are thus associated with the present location of the active shock regions. With respect to CO, H$_2$O emission appears more localized, having a less prominent diffuse component. About 60% of the total 179 μm flux is found within 30″ apertures centered on the knots. This could be partly related to the line excitation: the 179 μm line excitation temperature is $\sim 80$ K above the o-H$_2$O ground state (compared to the 17 K for CO 2−1), and the critical density of its upper level is above $10^8$ cm$^{-3}$ for $T \lesssim 500$ K. It may however also be a consequence of the specific conditions needed to ensure a significant production of water. The H$_2$O abundance is indeed significantly higher only in shocks strong enough to release the water ice located on grain mantles by sputtering and grain-grain collisions or to activate the gas-phase reactions that convert the gas-phase oxygen into water. Both these processes become efficient at shock velocities $v_s \gtrsim 15$ km s$^{-1}$ (Caselli et al. 1997; Jiménez-Serra et al. 2008; Kaufman & Neufeld 1996). In this respect, we note that the H$_2$O emission peaks correspond rather closely to both the position and the relative intensity of the H$_2$ rotational emission (with the H$_2$O 179 μm/H$_2$ 17 μm ratio in the range (2−3) $\times 10^{-5}$ for all the H$_2$ peaks). Peaks of low-J H$_2$ pure rotational lines are associated with warm gas (with $T \sim 300$−500 K) excited in low velocity non-dissociative shocks that are tracers of regions in which a high H$_2$O abundance is expected. Other molecules are known to have strongly enhanced abundances in shocks. One of the most well studied of these molecules is SiO, for which Fig. 1 shows that, like water, its emission is very localized around the shocked knots. A similar behavior is found for other molecules, such as NH$_3$ and CH$_3$OH (Bachiller et al. 2001; Tafalla & Bachiller 1995).

The strongest water peak is located at the position of the B1 knot, which is known to be the most chemically active of the L1157 spots (e.g. Bachiller & Perez-Gutierrez 1997; Benedettini et al. 2007; Codella et al. 2010). This knot at near-IR wavelengths appears as a bow shock with intense H$_2$ 2.12 μm emission (Davis & Eisloffel 1995) and has a significant H$_2$ column density enhancement (Nisini et al. 2010). Although the spatial resolution of the present observations prevents us from completely resolving the bow shock structure, the observed morphology at the B1/B0 positions suggests that water emission is mainly localized at the bow apex and eastern wing. A similar morphology has been observed for molecules such as SiO, NH$_3$, and CS (Benedettini et al. 2007; Tafalla & Bachiller 1997), while other shock produced molecules, such as CH$_3$OH, noticeably have emission localized on the bow western wing (e.g. Codella et al. 2009). This behavior probably relates to an asymmetry in the excitation conditions along the bow structure, most likely induced by the jet precession or the propagation of shocks in an inhomogeneous medium.

Strong, spatially unresolved, water emission is also detected on-source. This localized emission can originate in different components, including shocks impacting on a dense medium at the jet base, the infalling protostellar envelope, or emission from a UV-heated outflow cavity, as discussed in van Kempen et al. (2010) for the HH46-IRS case. The precise origin of this emission will be investigated by dedicated Herschel observations, but we note here the interesting evidence that no other molecule exhibits significant emission at the central position. In particular, the non-detection of strong emission from molecules such as CH$_3$OH indicates that grain ice mantle evaporation in the protostellar envelope is unlikely to be the origin of the on-source H$_2$O emission, since the two molecules should desorb at similar temperatures. The non-detection of the H$_2$ 0−0 S(1) line at the central position is also remarkable. This may be caused by the heavy extinction close to the central source. Assuming an intrinsic H$_2$O 179 μm/H$_2$ 17 μm ratio in the range of that observed along the outflow, we estimate that $A_v$ on-source should be $\gtrsim$150 mag to be able to explain the H$_2$ line non-detection. Alternatively, C-type shocks with very high pre-shock densities ($\gtrsim 10^3$ cm$^{-3}$) and velocities between 20 and 40 km s$^{-1}$ are expected to have a large H$_2$O/H$_2$ cooling ratio (Kaufman & Neufeld 1996).

4. Water abundance and total cooling

To constrain the range of water column densities that could produce the observed 179 μm emission, we consider the SWAS and Odin observations of the H$_2$O 1$_{10}$−1$_{01}$ 557 GHz (538 μm) line observed in this outflow (Franklin et al. 2008; Bjerck et al. 2009). Given the large size of the apertures of these two
B. Nisini et al.: Water cooling of shocks in protostellar outflows

Fig. 1. Continuum subtracted PACS map of the integrated H$_2$O 179 $\mu$m emission along the L1157 outflow. Offsets are with respect to the L1157-mm source, at coordinates $\alpha$(2000) = 20:39:06.2, $\delta$(2000) = +68:02:16. The different emission peaks are labelled following the nomenclature adopted by Bachiller et al. (2001) for individual CO peaks. The same map is shown in the other panels with overlays of other tracers, namely H$_2$ 0–0 S(1) at 17 $\mu$m (Neufeld et al. 2009), CO 2–1, and SiO 3–2 (Bachiller et al. 2001). The spatial resolution of these images are $\sim$11$''$, for H$_2$ and CO, and 18$''$ for SiO. Note that the H$_2$ observed region does not cover the B2 and R2 shocked peaks.

Fig. 2. LVG theoretical predictions of the 179 $\mu$m line brightness versus the 179 $\mu$m/557 GHz line ratio, compared with observed values. See text for the details.

Instruments relative to the PACS spatial resolution, we evaluate here only properties averaged over large outflow regions. In particular, we consider the Odin observations acquired towards the blue (B) and red (R) outflow lobes at offsets (+29$''$, −52$''$) and (−21$''$, +121$''$) (Bjerkeli et al. 2009). The 179 $\mu$m/557 GHz intensity ratios are obtained by diluting the PACS observations to the 126$''$ Odin resolution. The same procedure was adopted for the SWAS observation that encompasses almost the entire L1157 PACS mapped region with its 3.5$'$x5.0$'$ elliptical aperture.

Several general conclusions can be drawn from the inspection of Fig. 2. Firstly, the data are consistent with model predictions only if we assume that the real emitting areas are smaller than those estimated from the PACS map. In particular, agreement with the theoretical curves is found for covering factors ($f_c$) ~0.1–0.2, which suggests that the emission is...
concentrated on some unresolved emission knots that together do not fill an area larger than a few tens of arcsec. This is not unexpected, since interferometric mm observations illustrate the extreme clumpiness of the shocked gas, individual knots being of sizes of a few arcsec each (e.g., Benedettini et al. 2007; Lefloch et al. 2010). We note that the typical length scale for planar C-type shocks at the considered densities is of the order of 10^{16} cm, about 1/10 of the PACS spatial resolution at D = 440 pc. The observed 179 μm/557 GHz ratios, ranging between 10 and 20, are consistent with N(H2O) ~ 2–9 × 10^{16} cm^{-2} (assuming a Δv = 25 km s^{-1} from the 557 GHz line width). The H2 column densities, averaged within the PACS emitting areas, were measured from the H2 mid-IR rotational lines and results in ~5 × 10^{19} cm^{-2} in both regions covered by the B and R observations. The water abundance in the unresolved clumps is therefore estimated to be ~N(H2O)/N(H2) × f_w ~ 0.6–3 × 10^{-4} (with a H2O α/β ratio of 3). Table 1 reports in more detail the range of values derived in each considered aperture. The total mass of the shocked gas involved in the 179 μm emission is of the order of 5 × 10^{-3} M⊙, which is only a small fraction (~1/100) of the total mass of the outflow estimated from CO observations (e.g. Bachiller et al. 2001). Lefloch et al. (2010) show that H2O components with different velocities are discernible in the 557 GHz data acquired by HIFI in a 40″ beam centred on the L1157-B1 knot. They separately analyse the different clump components, confirming that small filling factors are required to explain their observations and finding that the component of higher velocity is the one exhibiting the water abundance of the order of 10^{-4}. Lower H2O abundance values, between 10^{-6} and 10^{-7}, were estimated using only the SWAS and Odin 557 GHz emission, assuming that the 557 GHz emission originates in the same cool gas traced by the low-J CO emission, thus a gas with a larger covering factor and lower temperature than considered here (Neufeld et al. 2000; Franklin et al. 2008; Bjerkeli et al. 2009). Combining ISO-179 μm emission and SWAS observations, Benedettini et al. (2002) derived a water abundance for the warm shocked gas of ~5 × 10^{-5}, thus in the lower range of values estimated in the present analysis. However, the ISO observations did not cover the entire L1157 outflow 179 μm emission, and the inferred ISO 179 μm/SWAS 557 GHz ratio was underestimated by about a factor of 2. Given the considered conditions, the 179 μm line contributes to about 30–40% of the water emission in the outflow: the total estimated H2O luminosity is ~8–9 × 10^{-2} L⊙, which is about 40% of the total H2 shock luminosity (0.2 L⊙, Nisini et al. 2010) and about 23% of the total shock cooling in the L1157 outflow, if we also consider the contributions given by CO and [O I] derived from ISO observations by Giannini et al. (2001). The high water abundance estimated in the present analysis is consistent with predictions of non-dissociative shock models, in which water is mainly produced by endothermic reactions, activated at T ≥ 300 K, where all the available gas-phase oxygen is converted into H2O, or by the sputtering of icy grain mantles behind the shock. According to Bergin et al. (1998), the time needed to complete this process is of the order of 10^{3} yr, for T = 400 K. This is comparable to the shock timescales estimated from H2 observations of individual emission knots of the L1157 outflow (Nisini et al. 2010), thus supporting the idea that the water in this outflow has had time to reach its maximum allowed abundance.

5. Conclusions

We have presented a PACS spectral map of the H2O 179 μm transition obtained toward the L1157 protostellar outflow. Strong water emission peaks have been found at the location of previously-known shocked spots and correlate well with H2 mid-IR rotational lines, as well as other important shock tracers, such as SiO and NH3. The absolute 179 μm intensity and the intensity ratios with respect to the previously-observed 557 GHz line, indicate that the water emission originates in warm compact clumps, spatially unresolved by PACS, that have a H2O abundance of the order of 10^{-4}. The total H2O cooling has been estimated to be of the order of 8–9 × 10^{-2} L⊙, representing about 40% of the cooling due to H2 and 23% of the total energy released in shocks along the L1157 outflow.

Additional Herschel PACS/HIFI observations of the L1157 outflow are planned by the WISH program. These will enable us to investigate variations in the water abundance within the outflow and correlate these with kinematical information.
