Water cooling of shocks in protostellar outflows

Herschel-PACS map of L1157*

(Affiliations are available in the online edition)

Received 31 March 2010 / Accepted 23 April 2010

ABSTRACT

Context. The far-IR/sub-mm spectral mapping facility provided by the Herschel-PACS and HIFI instruments has made it possible to obtain, for the first time, images of H₂O emission with a spatial resolution comparable to ground-based mm/sub-mm observations.

Aims. In the framework of the Water In Star-forming regions with Herschel (WISH) key program, maps in water lines of several outflows from young stars are being obtained, to study the water production in shocks and its role in the outflow cooling. This paper reports the first results of this program, presenting a PACS map of the ν=1-H₂O 179 μm transition obtained toward the young outflow L1157.

Methods. The 179 μm map is compared with those of other important shock tracers, and with previous single-pointing ISO, SWAS, and Odin water observations of the same source that allow us to constrain the H₂O abundance and total cooling.

Results. Strong H₂O peaks are localized on both shocked emission knots and the central source position. The H₂O 179 μm emission is spatially correlated with emission from H₂ rotational lines, excited in shocks leading to a significant enhancement of the water abundance. Water emission peaks along the outflow also correlate with peaks of other shock-produced molecular species, such as SiO and NH₃. A strong H₂O peak is also observed at the location of the proto-star, where none of the other molecules have significant emission.

Key words. stars: formation – ISM: jets and outflows – ISM: molecules

1. Introduction

Among the main coolants in molecular shocks, water is the tracer most sensitive to physical variations and the temporal evolution of protostellar outflows, thus representing a very powerful probe of their shock conditions and thermal history (e.g., Bergin et al. 1998). Water emission and excitation in shocks were studied extensively for the first time with ISO, the first space facility with spectroscopic capabilities in the mid- and far-IR. ISO surveyed the water emission in a large sample of outflows from young stellar objects (YSOs), providing a global statistical picture of variations in the outflow cooling and of variations in its abundance with shock properties and ages (see e.g., Nisini 2003; van Dishoeck 2004). Following ISO, the SWAS and Odin facilities made it possible to observe the ortho-H₂O fundamental line at 557 GHz, providing important constraints on the water abundance and kinematics in the cold outflow gas components (e.g., Franklin et al. 2008; Bjerkeli et al. 2009). All these facilities, however, had poor spatial resolution (i.e. greater than 80″), which did not allow one to locate the origin of the water emission nor study variations in abundances and excitation within individual flows.

In this framework, a sample of YSO outflows will be surveyed in different water lines by the PACS and HIFI instruments onboard the Herschel satellite, as part of the key program WISH (Water In Star-forming-regions with Herschel). This paper presents the first results obtained from this survey, consisting of a PACS map of the H₂O 212−101 179 μm line covering the

outflow of the protostar L1157-mm, obtained during the Herschel science demonstration phase. The 179 μm line is the transition connecting the lower two back-bone levels of ortho-H2O. It is therefore one of the brightest water lines expected in collisionally excited conditions, thus representing an ideal tracer of the water distribution in shocked regions. L1157 is a well known outflow driven by a low mass class 0 object (L1157-mm, Lbol = 8.3 L⊙, D = 440 pc, Froebrich 2005). It is considered to be the prototype of chemically active flows, given the large number of different species detected in its shocked regions (e.g., Bachiller & Perez-Gutierrez 1997). This paper is presenting the first of several observations planned for this source by the WISH team.

2. Observations

Observations were performed on 26 October 2009 with the PACS instrument (Poglitsch et al. 2010) onboard the Herschel Space Observatory (Pilbratt et al. 2010) in line spectroscopic mode, with the grating centred on the H2O 212−101 line at 179.527 μm. The L1157 outflow region (of about 6′ × 2′) was covered by 3 individual PACS raster maps, arranged along the outflow axis. Each map consists of 3 × 3 PACS frames acquired in steps of 40″. The instrument is a 5 × 5 pixel array providing a spatial sampling of 9.4″/pixel, while the spectral resolution at 179 μm is R ~ 1500 (i.e., ~210 km s−1). The data were reduced with HIPE 2.0. Additional IDL routines were developed to construct a final integrated and continuum-subtracted line map. Flux calibrations used calibration files obtained by ground tests that remain very uncertain at the time of paper writing, especially for extended sources. To evaluate the flux uncertainty, we compared with the three measurements performed by the ISO satellite along the outflow (Giannini et al. 2001). To do that, we performed aperture photometry of the line emission in the PACS map within the 80″ ISO circular beam. The ratio of PACS to ISO fluxes ranges between 1.1 and 1.8 at the three positions: we adopt this as the uncertainty in our quantitative analysis. The typical rms noise across the map is of the order of 2 × 10−6 erg s−1 cm−2 sr−1.

3. Results and comparison with other tracers

Figure 1 presents the PACS map of the 179 μm line emission. In the same figure, the H2O map is overlaid with contours of the emission from the H2 0–0 S(1) (Neufeld et al. 2009), CO 2–1 and SiO 3–2 (Bachiller et al. 2001) transitions. The water map exhibits several emission peaks corresponding to the positions of previously-known shocked knots, labelled as B0-B1-B2 for the south east blue-shifted lobe, and R0-R-R2 for the north west red-shifted lobe, following the nomenclature of Bachiller et al. (2001). These emission knots represent the actual working surfaces of a precessing and pulsed jet and are thus associated with the present location of the active shock regions. With respect to CO, H2O emission appears more localized, having a less prominent diffuse component. About 60% of the total 179 μm flux is found within 30″ apertures centered on the knots. This could be partly related to the line excitation: the 179 μm line excitation temperature is ~80 K above the H2O ground state (compared to the 17 K for CO 2–1), and the critical density of its upper level is above 106 cm−3 for T ≤ 500 K. It may however also be a consequence of the specific conditions needed to ensure a significant production of water. The H2O abundance is indeed significantly higher only in shocks strong enough to release the water ice located on grain mantles by sputtering and grain-grain collisions or to activate the gas-phase reactions that convert the gas-phase oxygen into water. Both these processes become efficient at shock velocities uS ≥ 15 km s−1 (Caselli et al. 1997; Jiménez-Serra et al. 2008; Kaufman & Neufeld 1996). In this respect, we note that the H2O emission peaks correspond rather closely to both the position and the relative intensity of the H2 rotational emission (with the H2O 179 μm/H2 17 μm ratio in the range (2−3) × 10−4 for all the H2 peaks). Peaks of low-J H2 pure rotational lines are associated with warm gas (with T ~ 300–500 K) excited in low velocity non-dissociative shocks that are tracers of regions in which a high H2O abundance is expected. Other molecules are known to have strongly enhanced abundances in shocks. One of the most well studied of these molecules is SiO, for which Fig. 1 shows that, like water, its emission is very localized around the shocked knots. A similar behavior is found for other molecules, such as NH3 and CH3OH (Bachiller et al. 2001; Tafalla & Bachiller 1995).

The strongest water peak is located at the position of the B1 knot, which is known to be the most chemically active of the L1157 spots (e.g. Bachiller & Perez-Gutierrez 1997; Benedettini et al. 2007; Codella et al. 2010). This knot at near-IR wavelengths appears as a bow shock with intense H2 2.12 μm emission (Davis & Eisloeffel 1995) and has a significant H2 column density enhancement (Nisini et al. 2010). Although the spatial resolution of the present observations prevents us from completely resolving the bow shock structure, the observed morphology at the B1/B0 positions suggests that water emission is mainly localized at the bow apex and eastern wing. A similar morphology has been observed for molecules such as SiO, NH3, and CS (Benedettini et al. 2007; Tafalla & Bachiller 1997), while other shock produced molecules, such as CH3OH, noticeably have emission localized on the bow western wing (e.g. Codella et al. 2009). This behavior probably relates to an asymmetry in the excitation conditions along the bow structure, most likely induced by the jet precession or the propagation of shocks in an inhomogeneous medium.

Strong, spatially unresolved, water emission is also detected on-source. This localized emission can originate in different components, including shocks impacting on a dense medium at the jet base, the infalling protostellar envelope, or emission from a UV-heated outflow cavity, as discussed in van Kempen et al. (2010) for the HH46-IRS case. The precise origin of this emission will be investigated by dedicated Herschel observations, but we note here the interesting evidence that no other molecule exhibits significant emission at the central position. In particular, the non-detection of strong emission from molecules such as CH3OH indicates that grain ice mantle evaporation in the protostellar envelope is unlikely to be the origin of the on-source H2O emission, since the two molecules should desorb at similar temperatures. The non-detection of the H2 0–0 S(1) line at the central position is also remarkable. This may be caused by the heavy extinction close to the central source. Assuming an intrinsic H2O 179 μm/H2 17 μm ratio in the range of that observed along the outflow, we estimate that A0 on-source should be ≥150 mag to be able to explain the H2 line non-detection. Alternatively, C-type shocks with very high pre-shock densities (≥106 cm−3) and velocities between 20 and 40 km s−1 are expected to have a large H2O/H2 cooling ratio (Kaufman & Neufeld 1996).

4. Water abundance and total cooling

To constrain the range of water column densities that could produce the observed 179 μm emission, we consider the SWAS and Odin observations of the H2O 1 00−1 01 557 GHz (538 μm) line observed in this outflow (Franklin et al. 2008; Bjerke et al. 2009). Given the large size of the apertures of these two
B. Nisini et al.: Water cooling of shocks in protostellar outflows

Fig. 1. Continuum subtracted PACS map of the integrated H$_2$O 179 $\mu$m emission along the L1157 outflow. Offsets are with respect to the L1157-mm source, at coordinates $\alpha(2000) = 20:39:06.2$, $\delta(2000) = +68:02:16$. The different emission peaks are labelled following the nomenclature adopted by Bachiller et al. (2001) for individual CO peaks. The same map is shown in the other panels with overlays of other tracers, namely H$_2$ 0–0 S(1) at 17 $\mu$m (Neufeld et al. 2009), CO 2–1, and SiO 3–2 (Bachiller et al. 2001). The spatial resolution of these images are $\sim 11''$ for H$_2$ and CO, and $18''$ for SiO. Note that the H$_2$ observed region does not cover the B2 and R2 shocked peaks.

In the figure, observations are indicated as boxes that take into consideration the uncertainty of a factor of about 1.5 in the 179 $\mu$m flux, estimated by comparing with the ISO observations (Sect. 2). Theoretical curves were derived as a function of the o-H$_2$O column density, using the RADEX code (Van der Tak et al. 2007) assuming temperature and density conditions measured from the H$_2$ Spitzer observations or ground-based millimeter observations (Nisini et al. 2010, 2007; Mikami et al. 1992). The temperature is between 300 and 500 K and the density is in the range $1 \times 10^5$ cm$^{-3}$, the blue lobe being on average colder and denser than the red lobe. Part of the 557 GHz emission can arise from a gas colder than these assumed values, given the lower excitation temperature of this line with respect to the 179 $\mu$m line.

To evaluate the effect of different temperature components along the line of sight on the ratio of the two considered transitions, Fig. 2 also plots the theoretical predictions assuming a temperature stratification where the column density in each layer at a given $T$ varies as $T^{-b}$ (Neufeld & Yuan 2008). A minimum and maximum temperature of 100 K and 4000 K, respectively are assumed, and $b$ values between 2 and 4, i.e., the range of values that consistently fit the H$_2$ rotational lines (Neufeld et al. 2009). These curves give the same range of predicted values as the single $T$ curves, indicating that contributions from high-temperature gas do not significantly affect the considered transitions.

Several general conclusions can be drawn from the inspection of Fig. 2. Firstly, the data are consistent with model predictions only if we assume that the real emitting areas are smaller than those estimated from the PACS map. In particular, agreement with the theoretical curves is found for covering factors ($f_c$) ~0.1–0.2, which suggests that the emission is

5. Conclusions

We have presented a PACS spectral map of the H2O 179 μm transition obtained toward the L1157 protostellar outflow. Strong water emission peaks have been found at the location of previously-known shocked spots and correlate well with H2 mid-IR rotational lines, as well as other important shock tracers, such as SiO and NH3. The absolute 179 μm intensity and the intensity ratios with respect to the previously-observed 557 GHz line, indicate that the water emission originates in warm compact clumps, spatially unresolved by PACS, that have a H2O abundance of the order of 10^{-4}. The total H2O cooling has been estimated to be of the order of 8–9 × 10^{-2} L⊙, representing about 40% of the cooling due to H2 and 23% of the total energy released in shocks along the L1157 outflow.

Additional Herschel PACS/HIFI observations of the L1157 outflow are planned by the WISH program. These will enable us to investigate variations in the water abundance within the outflow and correlate these with kinematical information.

Acknowledgements. This program is made possible thanks to the HIFI guaranteed time and the PACS instrument builders.
