### ABSTRACT

We report on observations of the unusual neutron-star binary system FIRST J102347.6+003841 carried out using the *XMM-Newton* satellite. This system consists of a radio millisecond pulsar (PSR J1023+0038) in a 0.198 day orbit with a  $\sim 0.2 M_{\odot}$  Roche-lobe-filling companion and appears to have had an accretion disk in 2001. We observe a hard power-law spectrum ( $\Gamma = 1.26(4)$ ) with a possible thermal component, and orbital variability in X-ray flux and possibly hardness of the X-rays. We also detect probable pulsations at the pulsar period (single-trial significance  $\sim 4.5\sigma$  from an 11(2)% modulation), which would make this the first system in which both orbital and rotational X-ray pulsations are detected. We interpret the emission as a combination of X-rays from the pulsar itself and from a shock where material overflowing the companion meets the pulsar wind. The similarity of this X-ray emission to that seen from other millisecond pulsar binary systems, in particular 47 Tuc W (PSR J0024–7204W) and PSR J1740–5340, suggests that they may also undergo disk episodes similar to that seen in J1023 in 2001.

*Key words:* pulsars: general – pulsars: individual (PSR J1023+0038) – stars: neutron – X-rays: stars

### 1. INTRODUCTION

Radio millisecond pulsars (MSPs) are thought to have been spun up to their current rapid rotation by a long period of accretion in a low-mass X-ray binary (LMXB). This general idea is well supported by many lines of evidence, but the transition between LMXB and radio millisecond pulsar remains mysterious. In particular, models of binary evolution often predict that mass transfer should continue indefinitely (Deloye 2008), but ionized material entering the magnetosphere of a neutron star (NS) is expected to “short out” magnetospheric emission (Stella et al. 1994). How then can we explain the observed radio millisecond pulsars?

The object FIRST J102347.6+003841 (hereafter J1023), discovered by Bond et al. (2002), was recently identified as an interesting system for studying this question. This source is now known to be a 0.198-day binary containing a 1.69-ms radio millisecond pulsar, PSR J1023+0038 (Archibald et al. 2009). This system is unique in that it shows evidence for having had an accretion disk as recently as 2001 (Szkody et al. 2003; Wang et al. 2009), but is now active as a radio pulsar. This suggests that we are observing the end of an LMXB phase and the birth of a radio millisecond pulsar, during which the system undergoes transient LMXB phases. This is consistent with a scenario put forward by Burderi et al. (2001) in which LMXBs, late in their evolution, may have episodes of mass transfer but spend most of their time in “radio ejection” phases, during which the wind from an active radio MSP sweeps material overflowing the companion out of the system.

In its current quiescent state, J1023 has been extensively observed with optical and radio telescopes. The millisecond pulsar’s companion appears as a  $V \sim 17$  mag star with a G-like absorption-line spectrum. The brightness and temperature show

a 0.198 day modulation consistent with heating due to an irradiation luminosity of roughly  $2 L_{\odot}$  from the primary (Thorstensen & Armstrong 2005). The combination of pulsar timing and optical radial velocity measurements shows that the mass ratio is 7.1(1), while assuming the pulsar mass is  $\sim 1.4 M_{\odot}$  implies an inclination angle of  $\sim 46^{\circ}$ , a companion mass of  $\sim 0.2 M_{\odot}$ , and, based on Roche-lobe size and optical apparent magnitude, a distance of  $\sim 1.3$  kpc (Archibald et al. 2009). At radio wavelengths, the system shows variable, frequency-dependent eclipses near the orbital phase at which the companion is closest to our line of sight to the pulsar, though the companion’s Roche lobe never actually intersects this line of sight. Irregular short eclipses are also observed at all phases (Archibald et al. 2009). Such variable radio eclipses have been observed in other millisecond pulsar systems, both in the so-called black widow systems in which the companion is thought to be a very low mass degenerate star being ablated by the pulsar wind (Fruchter et al. 1988; Stappers et al. 1996), and in several systems more similar to J1023, with companions that appear to be unevolved and Roche-lobe-filling (Freire et al. 2003; D’Amico et al. 2001). Comparison of J1023 with these systems, as well as with LMXBs in quiescence, could clarify how accretion comes to an end and radio pulsars become active.

Prior to the discovery that J1023 contained a millisecond pulsar, and unfortunately after it had returned to quiescence, Homer et al. (2006) observed J1023 with *XMM-Newton*. They concluded that it had a hard power-law spectrum, variability not necessarily correlated with the orbital phase, and a 0.5–10 keV X-ray luminosity of  $2.5 \times 10^{32}$  erg s<sup>-1</sup> ( $0.065 L_{\odot}$ ) at a distance, based on estimates available at the time, of 2 kpc. This supported the suggestion of Thorstensen & Armstrong (2005) that J1023 had a NS primary rather than a white dwarf as had previously been thought.

Not only does the detection of J1023 as a radio millisecond pulsar confirm that it is a NS binary, radio timing provides an ephemeris predicting the rotation of the pulsar. For this reason, we observed J1023 for a longer time and with high time resolution using *XMM-Newton*. Our observations confirm the spectral observations of Homer et al. (2006), show evidence for orbital variability, and show for the first time probable X-ray pulsations at the pulsar period.

In Section 2, we summarize the observations we used and our initial data reduction. In Section 3, we describe and give results from our spectral analysis and our search for orbital and rotational modulation in the X-ray data. In Section 4 we discuss the implications for the nature of J1023's X-ray emission and the relation of J1023 to similar systems, and in Section 5 we summarize and suggest further avenues of research.

## 2. OBSERVATIONS

The European Photon Imaging Camera (EPIC), aboard the *XMM-Newton* satellite, has two MOS cameras (Turner et al. 2001) and one PN camera (Strüder et al. 2001). All three cameras may be operated in an imaging mode, but the PN camera can also be run in a fast timing mode, in which the photons from one CCD are accumulated along one dimension, losing two-dimensional imaging, but achieving a time resolution of 29  $\mu$ s. Calibration uncertainties limit the absolute time accuracy of *XMM-Newton* to approximately 100  $\mu$ s (Guainazzi et al. 2010). *XMM-Newton* also has a coaxial optical telescope, the Optical Monitor, and two reflection grating spectrometers; however, J1023 is too faint to permit interesting studies with the latter.

We obtained an *XMM-Newton* observation (ObsID 0560180801) of J1023 of 33 ks, corresponding to 1.94 binary orbits, on 2008 November 26. We operated the PN camera in fast timing mode and the MOS cameras in “prime full window” (imaging) mode, and we used the thin filter on all the EPIC cameras. The data were free of soft proton flares, so we were able to use the entire exposure time. We also retrieved the data set (ObsID 0203050201) used by Homer et al. (2006) from the *XMM-Newton* archive; it consists of a single 16 ks exposure (0.92 binary orbits) obtained on 2004 May 12, with all EPIC instruments using “prime full window” mode and the thin filter. This data set is also free of soft proton flares, but since all three EPIC instruments were operated in imaging mode, in this case high-resolution timing data are not available.

The Optical Monitor was operated in both observations with the *B* filter and a mode with 10 s time resolution. Pipeline processing showed optical modulation consistent with that reported by Thorstensen & Armstrong (2005), so we did no further analysis of the optical data.

We analyzed the X-ray data with the *XMM-Newton* Science Analysis Software<sup>7</sup> version 9.0.0<sup>8</sup> and *xspec* version 12.5.0ac.<sup>9</sup>

We reprocessed the MOS and PN data with the *emchain* and *epchain* pipelines, respectively, then extracted photons meeting the recommended pattern, pulse invariant, and flag criteria. In particular, this restricted MOS photons to the 0.2–12 keV energy range, PN imaging photons to the 0.13–15 keV energy range, and PN timing photons to the 0.25–15 keV energy range. For all analyses except the spectral fitting, we restricted the

imaging photons from either type of camera to 0.2–10 keV for consistency, since this involved discarding only a handful of photons.

The default pipeline processing showed no evidence for extended emission from J1023, so we used the SAS tool *eregionanalyse* to select extraction regions to optimize the ratio of source photons to the square root of source plus background photons. These regions were circles of radius 35'' (enclosing about 90% and 85% of the 1.5 keV flux on the MOS and PN cameras, respectively) in imaging observations. For the timing-mode PN observation, we adjusted the extraction region by hand to optimize detection significance (see below), selecting a band 12'' wide (enclosing about 60% of the 1.5 keV flux). We selected background regions from nearby large circles in the imaging-mode observations, and from a band 50'' wide, to one side of the source, in the timing-mode PN data. All together, this yielded approximately 5700 background-subtracted source photons in imaging mode and approximately 2400 background-subtracted source photons in timing mode.

We computed photon arrival times using the SAS barycentering tool, *barycen*, the precise optical position 10<sup>h</sup>23<sup>m</sup>47<sup>s</sup>.67 +0°38'41".2 (J2000) given in the NOMAD catalog (Zacharias et al. 2004), and the DE405 solar system ephemeris. To produce pulsar rotational phases during the 2008 observation, we used the tool *tempo*<sup>10</sup> and the ephemeris given in Archibald et al. (2009), which is based on radio pulsar timing data bracketing the X-ray observation epoch. The extremely sensitive phase-coherent timing procedure used by Archibald et al. revealed minuscule variations in the orbital period of J1023. These are modeled in the published ephemeris by expressing the orbital period as a quadratic polynomial obtained by a fit to several months of 2008 timing data. Extrapolating this polynomial back to the 2004 *XMM-Newton* observation results in an unreasonable and poorly constrained orbital period at the time of  $\sim -6$  days, a clear indication that the orbital period variations are not actually given by such a quadratic polynomial. While it is necessary to model the orbital period derivatives to obtain good quality *pulsar* phase predictions, it is possible to obtain adequate *orbital* phase predictions by using a simple model with constant orbital period of 0.19809620 days and (pulsar) ascending node of MJD 54801.970652993, based on the model from Archibald et al. (2009). This model gives adequate orbital phase predictions back to 2004, matching the orbital phases observed in Thorstensen & Armstrong (2005) to within 1% of a period as well as matching the ephemeris given in Archibald et al. (2009) exactly on 2008 December 1. We therefore used this model to evaluate the orbital phase of each barycentered photon in both our observations.

## 3. RESULTS

### 3.1. Spectral Fitting

We used *xspec* to fit each of several models to all EPIC imaging data sets from both epochs simultaneously. To verify that the data sets were compatible, we also fit different absorbed power laws to the two observations, obtaining compatible spectral indices and normalizations. For the MOS cameras, we restricted photons to the recommended energy range, namely, 0.2–10 keV, and for the PN camera we used the recommended lower limit of 0.13 keV but used the upper limit of 10 keV as there were not enough photons above this to provide any

0.5–10 keV luminosity <sup>a</sup> ( $\text{erg s}^{-1}$ )	$9.4(4) \times 10^{31}$	$9.9(5) \times 10^{31}$
Thermal fraction	...	0.06(2)
$\chi^2/\text{degrees of freedom}$	230/214	208/212
Null hypothesis probability	0.21	0.56

**Note.** <sup>a</sup> Assuming a distance of 1.3 kpc.

**Figure 1.** Absorbed neutron-star atmosphere plus power-law spectral fit to all EPIC imaging-mode photons from both observations. Each data set is plotted in a different color: black is the 2004 MOS1, red the 2004 MOS2, green the 2004 PN, blue the 2008 MOS1, and cyan is the 2008 MOS2 data set. The vertical axis is normalized by the effective area, and the expected responses from the two additive components are overplotted separately (the harder component is the power law). The lower panel is the ratio of model predicted flux to observed flux in each group of detector channels.

(A color version of this figure is available in the online journal.)

constraint. We grouped the photons to obtain at least 20 counts per spectral bin so as to have approximately Gaussian statistics.

We obtained an adequate fit to all imaging data sets with a power-law model including photoelectric absorption. We did not obtain adequate fits with an absorbed single blackbody ( $\chi^2 = 1203.7$  with 213 degrees of freedom, for a null hypothesis probability of  $\sim 10^{-138}$ ) or neutron-star atmosphere model ( $\chi^2 = 1007.1$  with 213 degrees of freedom, for a null hypothesis probability of  $\sim 10^{-103}$ ).

The simple power-law model, with a photon index of 1.26(4), already has a null hypothesis probability of 0.21, which is satisfactory from a statistical point of view. Although the statistics do not call for a thermal component, we may expect one on physical grounds (for example from the surface of the neutron star). We therefore also consider an absorbed neutron-star atmosphere plus power-law model to fit these data, as shown in Figure 1. This model, specified in *xspec* as *phabs(nsa+pow)*, is based on Zavlin et al. (1996). During fitting we froze the neutron-star mass at  $1.4 M_{\odot}$  and the radius at 10 km for the purposes of redshift and light bending; the smaller effective thermal emission radius suggests that the emission comes from a small “hot spot” on the surface. In light of the fact that the

estimated  $B < 10^8$  G (Archibald et al. 2009), we also selected a model in which the magnetic field has negligible effects on the atmosphere, i.e.,  $\lesssim 10^9$  G.

These two models are summarized in Table 1. Uncertainties given are 90% intervals returned by *xspec*’s error command; luminosities are obtained by using the *cfux* model component to estimate unabsorbed and thermal fluxes in the 0.5–10 keV range and then using an assumed distance of 1.3 kpc to determine a luminosity. “Thermal fraction” is the fraction of this luminosity due to the thermal component of the spectrum, if any.

In both cases, fitting for photoelectric absorption in the model gave a very low upper bound on the neutral hydrogen column density, as noted in Homer et al. (2006). Such a low value is to be expected since the entire Galactic column density in this direction is estimated<sup>11</sup> to be only  $1.9 \times 10^{20} \text{ cm}^{-2}$  (based on Kalberla et al. 2005).

Although both models are statistically adequate, the Akaike information criterion (Akaike 1974) suggests one should prefer the model containing a thermal component. The *F* test gives a null probability of  $2 \times 10^{-5}$  that the more complex model would produce such a large improvement in fit due to chance if the simple power-law model were correct. While there are concerns with using the *F* test in such a situation (Protassov et al. 2002, but see also Stewart 2009) it appears that the statistics do somewhat favor a model with a thermal component, although a purely nonthermal model cannot be excluded.

### 3.2. Orbital Variability

To test for orbital variability, we selected 0.2–12 keV source photons from the imaging-mode data sets in both our observations and those of Homer et al. (2006) and reduced them to the solar system barycenter. When combining data from multiple instruments, to take into account the different orbital coverages and sensitivities, we weighted bin values so that all average count rates match that observed in the MOS1 camera in the same observation. For the hardness ratio analysis, we omitted the PN data so that their different energy response and incomplete orbital coverage would not skew the results.

A weighted histogram of these counts is shown in Figure 2, along with a best-fit sinusoid based on a finely binned profile. We selected four sinusoids as this appears to give a good representation of the curve and a time resolution similar to the histogram. A Kuiper test (Paltani 2004) gives a probability of  $1.3 \times 10^{-19}$  ( $9.0\sigma$ ) that photons drawn from a uniform

<sup>11</sup> Using the HEASARC online calculator, <http://heasarc.nasa.gov/cgi-bin/Tools/w3nh/w3nh.pl>

**Figure 2.** Panel (a): average MOS-equivalent count rate in the 0.2–12 keV energy range as a function of orbital phase. These data are a weighted average of all the imaging-mode data. Dashed and dotted vertical lines indicate the beginning and end of the 1.4 GHz radio eclipse, respectively. The dashed curve is a best-fit combination of four sinusoids. Panel (b): the number of MOS photons in the 1–12 keV range divided by the number of MOS photons in the 0.2–1 keV range, also as a function of orbital phase. Both panels show two cycles for clarity. The companion’s closest approach to our line of sight to the pulsar happens at orbital phase 0.25; that the radio eclipse is off-center may be due to eclipsing material being far out of the orbital plane, as shown in Figure 5.

distribution in orbital phase would be this non-uniform; the reduced  $\chi^2$  for a constant fit to the histogram is 11.3, with 11 degrees of freedom. While the evidence for variability is strong, with only  $\sim 3$  orbits covered by the two observations it is not certain that this variability is linked to orbital phase, although the fact that the minimum in the X-ray light curve occurs near orbital phase 0.25, when the companion passes closest to our line of sight to the pulsar, suggests a link. To test this, we plotted the photon arrival rates for each orbital period separately. Figure 3 shows that the flux during each individual orbit appears to be lower during phase 0–0.5 than during phase 0.5–1, which suggests that the variability is indeed orbital. Note that Homer et al. (2006) detected variability, but having only limited orbital coverage, could not determine whether it was orbital. We also computed a hardness ratio (Figure 2(b)), dividing the number of photons harder than 1 keV by the number of photons softer than 1 keV and comparing the eclipse versus non-eclipse regions (for this purpose we defined the “eclipse” region to be phases 0–0.5). The reduced  $\chi^2$  for a fit of these values to a constant hardness ratio is 8.76 for 1 degree of freedom, and the probability of such a reduced  $\chi^2$  arising if the hardness ratio were constant is  $3.1 \times 10^{-3}$  ( $2.7\sigma$ ). Thus, we see marginally significant softening in the eclipse region.

**Figure 3.** Average count rate in the 0.2–12 keV energy range as a function of orbital phase, for each orbit independently; the starting MJD for each orbit is indicated. The vertical axis is MOS-equivalent count rate (based on MOS1/2 and imaging-mode PN data, scaled to match the MOS1 count rate) and the dashed horizontal line indicates the average count rate over all orbital phases and data sets. Where no bar is plotted, no data are available.

### 3.3. Pulsations at the Pulsar Period

To test for pulsations, we extracted source and background photons from the PN camera using the energy range 0.25–2.5 keV, selected to give the most significant detection. We barycentered the photon arrival times and used the program *tempo*<sup>12</sup> and the contemporaneous radio ephemeris given in Archibald et al. (2009) to assign each photon a rotational phase (see Figure 4). We then tested these photons for uniform distribution in phase. The Kuiper test (Paltani 2004) gave a (single-trial) null hypothesis probability of  $3.7 \times 10^{-6}$  ( $4.5\sigma$ ) and the  $H$  test (de Jager et al. 1989) gave a (single-trial) null hypothesis probability of  $2.4 \times 10^{-6}$  ( $4.6\sigma$ ), using an optimal number of sinusoids (two). We confirmed that no significant pulsations were detected with the background photons or with an incorrect ephemeris. We also verified that the period predicted by the ephemeris is very close to the period at which the significance peaks (holding all other ephemeris parameters fixed).

<sup>12</sup> <http://www.atnf.csiro.au/research/pulsar/tempo/>

**Figure 4.** Panel (a) shows a background-subtracted light curve based on 0.25–2.5 keV PN photons folded according to the radio ephemeris; the sinusoid (drawn with a dotted line) is a two-component sinusoid fit to the unbinned photon arrival times. Panel (b) shows a 1400 MHz profile obtained with Arecibo (Archibald et al. 2009). Both panels show two cycles for clarity. The uncertainty in relative alignment, due primarily to the absolute timing uncertainty in the *XMM-Newton* data, is indicated by the horizontal error bar. The 20  $\mu$ s uncertainty relative to the radio data due to dispersion measure uncertainty is relatively unimportant.

To estimate the degree to which the X-ray flux is modulated at the pulse period, one could simply take the lowest bin in the histogram as the background level and compute the fraction of photons above it; this yields a pulsed fraction of 0.27(9). However, this method is subject to large uncertainties, dependence on binning, and a large statistical upward bias due to the fact that we selected the bin in which signal plus noise is lowest, rather than that in which the (unknown) signal is lowest. To avoid these problems, we define a root-mean-squared pulsed flux by fitting a model  $F(x)$  with two sinusoids:

$$f_{\text{RMS}} = \sqrt{\int_0^1 (F(x) - \bar{F})^2 dx},$$

where  $\bar{F}$  is the model mean flux. This is in some sense a degree of modulation; if the signal consists of a constant background plus a variable emission process that drops to zero, this is not directly measuring the fraction of emission

due to the variable process. (There is a conversion factor that depends on the exact shape of the pulse profile.) However, this quantity can be computed with substantially less uncertainty and bias. Computationally, we estimate the root-mean-squared amplitude in the Fourier domain, based on the amplitudes of the two complex Fourier coefficients (since higher-order Fourier coefficients are dominated by noise); since noise always contributes a positive power to Fourier coefficients, to reduce the bias we subtract the expected contribution of noise from the squared amplitude of each coefficient before taking the square root. We then convert this pulsed flux value to a pulsed fraction by dividing by the total background-subtracted flux from J1023.

For the energy range 0.25–2.5 keV, we estimate a root-mean-squared pulsed fraction of 0.11(2). In the two subbands 0.25–0.6 keV and 0.6–2.5 keV, we find root-mean-squared pulsed fractions of 0.17(5) and 0.14(3), respectively, with profiles that are broadly similar and in phase. Above 2.5 keV we find no evidence for pulsations, though a  $3\sigma$  upper limit on the pulsed fraction is only 0.20.

#### 4. DISCUSSION

To summarize our results for J1023, we observed an X-ray spectrum dominated by a hard power-law component, possibly with a small, soft, thermal contribution. The emission appears to be modulated at the 0.198 day orbital period, with substantial dips as the companion passes near the line of sight; these dips are accompanied by a possible softening in the spectrum. We also found that the X-ray emission is very likely modulated at the 1.69 ms rotational period of the radio pulsar.

##### 4.1. Nature of the X-ray Emission

In a review of X-ray emission from millisecond pulsars, Zavlin (2007) describes three primary sources of X-ray emission: emission from an intrabinary shock, emission from the neutron star itself, which is some combination of thermal and magnetospheric emission, and emission from a pulsar wind nebula outside the binary system. As all these mechanisms may be operating in J1023, we next consider their contributions, if any, to the observed X-rays from this system.

##### 4.1.1. Emission from an Intrabinary Shock

J1023 likely has a strong pulsar wind, since the optical data suggest that the companion is being heated by a luminosity of  $\sim 2 L_{\odot}$  from the pulsar (Thorstensen & Armstrong 2005). This is much greater than the X-ray luminosity of the system ( $\sim 0.03 L_{\odot}$ ), but well below the upper limit ( $\sim 80 L_{\odot}$ ) on the spin-down luminosity of the pulsar (Archibald et al. 2009). If material is leaving the companion, either through Roche-lobe overflow or a stellar wind, we should expect an intrabinary shock, where this flow meets the pulsar wind. Such a shock could readily produce power-law X-ray emission (Arons & Tavani 1993). If localized, it could easily account for the orbital modulation we observe in the X-ray emission. If the emission were due to Roche-lobe-overflowing material meeting the pulsar wind we might expect it to be localized at or near L1. Given the system geometry described in Archibald et al. (2009) (a  $46^{\circ}$  inclination angle, corresponding to a pulsar mass of  $1.4 M_{\odot}$ , and a Roche-lobe-filling companion; see Figure 5), the L1 point itself is eclipsed by the companion for 0.32 of the orbit, centered on orbital phase 0.25. We would expect spectral softening during this period, since the relatively hard power-law emission is blocked but the, presumably softer, emission from the neutron

**Figure 5.** J1023 system geometry at phase 0.25 as seen from within the plane of the sky. The system orbit is in and out of the page, the dashed line is our line of sight to the pulsar, and the dotted line is our line of sight to L1, which is eclipsed by the Roche-lobe-filling companion. The pulsar is indicated by a not-to-scale circle, but the companion is drawn to scale. The tick mark on the line connecting pulsar and companion marks the center of mass of the system. This system geometry assumes a pulsar mass of  $1.4 M_{\odot}$ ; a higher mass would mean a larger system seen more nearly face-on, but the range of plausible angles is constrained to  $\sim 53^{\circ}$ – $34^{\circ}$  by the narrow range of plausible pulsar masses  $1.0$ – $3.0 M_{\odot}$  (Archibald et al. 2009). Note that at this orbital phase the X-rays are near their minimum, and low radio frequencies from the pulsar are eclipsed, indicating the presence of ionized material well out of the orbital plane.

star is not. A larger X-ray-emitting region, due either to material streaming away from the L1 point or to a stellar wind shock, would result in a broader, shallower, and potentially asymmetric dip in the X-ray light curve.

The possibility of a wind from the companion is interesting, since it is not clear how Roche-lobe overflow would provide the ionized material causing the radio eclipses, which occur well above the orbital plane, roughly centered on the companion’s closest approach to our line of sight. Archibald et al. (2009) reported dispersion measure (DM) changes of  $\sim 0.15 \text{ pc cm}^{-3}$  above a cutoff frequency of  $\sim 1 \text{ GHz}$  at radio eclipse ingress and egress. Assuming that this is the plasma frequency implies an electron density of  $\sim 10^{10} \text{ cm}^{-3}$ ; combined with the excess DM measurement, this implies a layer of thickness  $\sim 4 \times 10^7 \text{ cm}$ , relatively thin compared to the orbital separation of  $1.2 \times 10^{11} \text{ cm}$ . This thin sheet of material could in principle arise as the shock front where the pulsar wind meets a wind from the companion, but it is difficult to explain the companion’s wind being strong enough to support such a shock: given the line-of-sight geometry of the system, the material causing the radio eclipses must be about as far from the companion as it is from the pulsar. If we assume that the highly relativistic pulsar wind provides the  $\sim 2 L_{\odot}$  required by the companion heating models of Thorstensen & Armstrong (2005), it seems difficult to explain how the companion could have a wind of comparable pressure anywhere along the line of sight. Thus, the radio eclipses remain a mystery, and Roche-lobe overflow seems a more likely explanation for the origin of the intrabinary shock.

#### 4.1.2. Emission from the Neutron Star

Some millisecond pulsars, binary or isolated, have X-ray emission modulated at the rotational period. This emission is some combination of magnetospheric emission, from high-energy particles in the magnetosphere, and thermal emis-

sion, from polar caps heated by bombardment by high-energy particles moving along the open field lines. Observationally, Zavlin (2007) draws the distinction that magnetospherically dominated emission has high pulsed fractions, narrow peaks, and power-law spectra, while polar-cap-dominated emission has lower pulsed fractions, broader peaks, and thermal spectra. Zavlin also suggests that pulsars with spin-down luminosities  $\gtrsim 10^{35} \text{ erg s}^{-1}$  tend to be magnetospherically dominated while those with spin-down luminosities  $\lesssim 10^{34} \text{ erg s}^{-1}$  tend to be thermally dominated, but since few examples are known, this classification is tentative, and the spin-down luminosity from J1023 is only known to be  $< 3 \times 10^{35} \text{ erg s}^{-1}$  (Archibald et al. 2009). In any case, classification of the pulsations we observe in J1023 is difficult.

In systems in which thermal emission from the neutron star provides all the detectable X-rays, detailed modeling indicates that the pulsed fraction should normally be  $\lesssim 50\%$  (that is, pulsed emission must be accompanied by roughly equal or greater unpulsed emission) due to light bending and the large size of the polar caps, though for certain combinations of parameters higher pulsed fractions can occur (Bogdanov et al. 2008). If the pulsations are purely thermal, then our spectral upper limit on the thermal fraction of 0.06(2) is difficult to reconcile with the fact that we observe a fractional modulation of 0.11(2) at the pulsar period. Thus, it seems likely that at least some magnetospheric emission is present, as it has a nonthermal spectrum and can more readily have higher pulsed fractions. The poor signal-to-noise in our observations, due to the high background (from the system itself as well as instrumental) and the scarce photons, makes it impractical to determine the sharpness of the pulse profile or the hardness of the pulsations. In any case the pulsations, if real, are a clear sign of X-ray emission from the pulsar itself.

#### 4.1.3. Emission from a Pulsar Wind Nebula

Nebular emission from pulsars arises when the particle wind driven by the pulsar’s magnetospheric activity flows out of the pulsar’s immediate neighborhood and meets the surrounding medium; for reviews see Gaensler & Slane (2006) or Kaspi et al. (2006). Pulsars like J1023 whose wind is confined by the ambient interstellar medium exhibit nebular emission that generally takes a cometary form, with an arc-like bow shock preceding the pulsar and a “trail” of ejected material streaming back along the pulsar’s track.

The angular size of bow shock emission depends on the pulsar’s spin-down luminosity, its proper motion, and the local interstellar medium density. Kargaltsev & Pavlov (2008) give a formula for predicting the “stand-off” angle of the X-ray bow shock from the pulsar:

$$\theta = 5''.4 n_{0.1}^{-1/2} \mu_{19}^{-1} \dot{E}_{35}^{1/2} D_{1.3}^{-2},$$

where  $n_{0.1}$  is the mean density of the interstellar medium divided by  $0.1 \text{ cm}^{-3}$ ,  $\mu_{19}$  is the proper motion divided by  $19 \text{ mas yr}^{-1}$ ,  $\dot{E}_{35}$  is the spin-down luminosity divided by  $10^{35} \text{ erg s}^{-1}$ , and  $D_{1.3}$  is the distance to J1023 divided by  $1.3 \text{ kpc}$ . We have supplied best-guess parameters for J1023 (Archibald et al. 2009), so that absent further information, we might expect a stand-off distance of  $\sim 5''$  for the X-ray bow shock. Thus, although nebular emission is not resolved in our *XMM-Newton* images, higher-resolution images with the *Chandra X-ray Observatory*, or in the H $\alpha$  or radio bands, might yet resolve a bow shock.

Kargaltsev & Pavlov (2008) find that the ratio of neutron-star emission to nebular emission generally lies between  $\sim 0.1$  and 10, which suggests that nebular emission may produce some of the X-rays we observe. Moreover, Kargaltsev & Pavlov find that nebular emission from bow shocks has a power-law spectrum with photon indices  $1 \lesssim \Gamma \lesssim 2$  (Kargaltsev & Pavlov 2008), consistent with what we observe from J1023, though the latter is somewhat harder than most pulsar wind nebulae. The orbital variability, on the other hand, argues against that component of the emission arising from an extrabinary pulsar wind nebula.

#### 4.2. Comparison to Similar Systems

In quiescence, most LMXBs have spectra that are dominated by thermal emission from the neutron star. This emission is typically consistent with a hydrogen atmosphere model with effective radius  $\sim 10$  km (Brown et al. 1998). Some LMXBs in quiescence also have a small power-law component of photon index  $1 \lesssim \Gamma \lesssim 2$  in their spectrum (Campana et al. 1998), while a few quiescent LMXBs have spectra completely dominated by this nonthermal component. For example, the quiescent LMXB SAX J1808.4–3658 has a spectrum that is a fairly hard power law with no detectable thermal emission (Heinke et al. 2009). J1023 resembles this latter category, although if a thermal component is present its effective radius appears to be substantially less than 10 km and the power-law spectral index is fairly hard. On the other hand, J1023’s radio and possible X-ray pulsations distinguish it from all known quiescent LMXBs.

SAX J1808.4–3658 is of particular interest because it is the prototype and best-studied example of a class of LMXBs from which millisecond X-ray pulsations have been detected during active phases. Many authors have suggested that SAX J1808.4–3658 should turn on as a radio pulsar during quiescence (e.g., Wijnands & van der Klis 1998; Chakrabarty & Morgan 1998; Campana et al. 2004), but no radio pulsations have been detected in spite of thorough searches (e.g., Burgay et al. 2003; Iacolina et al. 2009). The non-detection of radio pulsations could be because SAX J1808.4–3658 is shrouded by previously ejected ionized material or it could simply be an issue of unfortunate beaming. In any case, it is natural to compare SAX J1808.4–3658 to J1023.

During its active phases, SAX J1808.4–3658 reaches a sustained luminosity of  $\sim 4 \times 10^{36}$  erg  $s^{-1}$  (Galloway & Cumming 2006), in sharp contrast to the upper limit of  $2 \times 10^{34}$  erg  $s^{-1}$ , available for J1023 during its disk phase (Archibald et al. 2009). In its quiescent state, SAX J1808.4–3658 shows X-ray emission dominated by a hard power law ( $\Gamma = 1.74(11)$ ), with a small ( $\lesssim 0.1$ ) fraction of thermal emission, and a total X-ray luminosity of  $7.9(7) \times 10^{31}$  erg  $s^{-1}$  (Heinke et al. 2009). This is somewhat similar to what we observe in J1023, which has a total luminosity of  $9.9(5) \times 10^{31}$  erg  $s^{-1}$ , although the spectral index of 1.26(4) is somewhat harder than that seen from SAX J1808.4–3658. If J1023 has a thermal component, its power law is substantially harder, with a spectral index of 0.99(11). The thermal component would have an effective radius of  $0.7^{+0.5}_{-0.1}$  km and supply 0.06(2) of the total luminosity. While the spectral index seen in J1023 is harder than that seen from SAX J1808.4–3658, it is in line with the hard spectral indices seen from other X-ray-detected radio millisecond pulsars (for example, 47 Tuc W, though PSR J1740–530 is softer; see below). Since SAX J1808.4–3658 is known to cool quickly, even thermal X-ray pulsations in quiescence would be evidence of magnetospheric activity heating its polar caps. Campana et al. (2002) searched for such X-ray pulsations from SAX J1808.4–3658 in quies-

cence, but were unable to conduct meaningful searches due to its faintness; SAX J1808.4–3658 is roughly 3.5 kpc away (Galloway & Cumming 2006) compared to the roughly 1.3 kpc we assume for J1023 (Archibald et al. 2009).

The similarity of the X-ray properties of SAX J1808.4–3658 in quiescence to those of J1023 suggests that SAX J1808.4–3658 may indeed harbor a radio millisecond pulsar in quiescence; conversely, the same similarity suggests that J1023 may undergo episodes of active accretion.

Among radio pulsars, the two best-studied examples which closely resemble J1023 are 47 Tuc W (Bogdanov et al. 2005) and PSR J1740–5430 (D’Amico et al. 2001). Both pulsars exhibit large, variable radio-frequency eclipses and both are thought to have somewhat massive unevolved companions ( $\gtrsim 0.13 M_{\odot}$  and  $0.19\text{--}0.8 M_{\odot}$ , respectively). For comparison, J1023’s companion is thought to be  $\sim 0.2 M_{\odot}$  and shows a spectrum characteristic of a main-sequence star (Archibald et al. 2009; Thorstensen & Armstrong 2005). The radio eclipses are in all three cases evidence for material leaving the companion and presumably being expelled from the system, and in all three cases the companion appears to fill and perhaps overflow its Roche lobe (Bogdanov et al. 2005; Ferraro et al. 2001; Thorstensen & Armstrong 2005).

Bogdanov et al. (2005) studied 47 Tuc W and found an X-ray spectrum consisting of a dominant hard power law ( $\Gamma = 1.14(35)$ , contributing  $\sim 75\%$  of the total flux) plus a thermal component. They also observed orbital variability, and in particular a substantial X-ray eclipse spanning phases<sup>13</sup> 0.15–0.45 and centered slightly ahead of the optical minimum, at phase 0.2. This is accompanied by substantial softening of the X-ray spectrum during eclipse. Given these observations, Bogdanov et al. suggest that the power-law X-ray emission originates from a shocked region where material overflowing from the companion of 47 Tuc W meets the pulsar wind and is blown out of the system. Bogdanov et al. (2010) studied *Chandra X-ray Observatory* observations of PSR J1740–5430. Although limited by the scarcity of photons, they found a spectrum consistent with a power law of index  $\Gamma = 1.73(8)$  or with a somewhat harder power law plus a blackbody component. Their estimates of variability were limited by restricted orbital coverage as well as by a paucity of photons, but they found marginal evidence for orbital modulation, in particular a possible decrease in luminosity during the radio eclipses, possibly accompanied by a softening. Our observations of J1023 are more photon starved than those of Bogdanov et al. (2005) of 47 Tuc W, but we do see evidence for eclipses, and possibly for softening during eclipses. In the case of J1023, the possibility of overflowing gas is supported by the recent disk phase.

The similarity of the observational properties of these three millisecond pulsars suggests that their companions are all overflowing their Roche lobes, so that mass flows through the L1 point, where it encounters the pulsar wind and is swept away. On the other hand, the similarity also suggests the possibility that like J1023, 47 Tuc W or PSR J1740–5430 may undergo episodes in which the mass transfer rate from the companion increases and an accretion disc forms. Such episodes would presumably be signaled by optical changes, possibly by extinction of the radio pulsations, and presumably by modest X-ray brightening. All together, these observations suggest that as a system reaches the end of its life as an LMXB,

<sup>13</sup> Note that these authors use a different convention for orbital phase, setting phase 0.5 to the optical minimum, while we set phase 0.25 to the optical minimum. All phases given here have been converted to our convention.

its accretion rate drops and the millisecond pulsar becomes active. After this point, the wind from the pulsar generally prevents mass leaving the companion from forming an accretion disk or entering the pulsar magnetosphere. Temporary increases in the mass accretion rate may allow the occasional suppression of the wind and formation of an accretion disk, as was observed in J1023 in 2001.

## 5. CONCLUSIONS

J1023 shows X-ray emission probably consisting primarily of emission from an intrabinary shock, plus a smaller amount of emission from the pulsar itself and possibly some unresolved nebular emission. The shock emission shows substantial variability that appears to be linked to orbital phase, as well as possible spectral softening during eclipses. Similarities to 47 Tuc W and PSR J1740–5340 suggest that this may be due to gas overflowing from the companion meeting the pulsar wind in a shock close to the companion. The emission from the pulsar itself, if real, is probably due to some combination of curvature radiation in the magnetosphere and thermal radiation from polar caps heated by high-energy particles streaming downward, though which effect dominates is unclear. Further observations to provide improved spectra should help clarify the origin of both pulsed and unpulsed emission, as would further high-time-resolution observations to allow better measurement of pulse profiles, pulsed hardness ratios, and orbital variations of pulsed fraction. X-ray observations with higher spatial resolution might also resolve extended nebular emission around J1023. Better understanding of this object promises to clarify the transition from LMXB to radio millisecond pulsar and may show that other known systems are currently in this fascinating transition state.

The authors thank Mallory S. E. Roberts for useful discussions. This work was based on observations obtained with *XMM-Newton*, an ESA science mission with instruments and contributions directly funded by ESA Member States and NASA.
