During their asymptotic giant branch evolution, low-mass stars lose a significant fraction of their mass through an intense wind, enriching the interstellar medium with products of nucleosynthesis. We observed the nearby oxygen-rich asymptotic giant branch star IK Tau using the high-resolution HIFI spectrometer onboard Herschel. We report on the first detection of H$_{16}$O and the rarer isotopologues H$_2^{17}$O and H$_2^{18}$O in both the ortho and para states. We deduce a total water content (relative to molecular hydrogen) of 6.6 $\times$ 10$^{-5}$, and an ortho-to-para ratio of 3:1. These results are consistent with the formation of H$_2$O in thermodynamical chemical equilibrium at photospheric temperatures, and does not require pulsationally induced non-equilibrium chemistry, vaporization of icy bodies or grain surface reactions. High-excitation lines of $^{12}$CO, $^{13}$CO, 28SiO, 29SiO, 30SiO, HCN, and SO have also been detected. From the observed line widths, the acceleration region in the inner wind zone can be characterized, and we show that the wind acceleration is slower than hitherto anticipated.

**Key words.** line: profiles – radiative transfer – instrumentation: spectrographs – stars: AGB and post-AGB – circumstellar matter – submillimeter: stars

1. Introduction
IK Tau, also known as NML Tau, is an extremely red, oxygen-rich, Mira-type variable, with a period of about 470 days (Wing et al. 1973). Its dust-driven wind produces a cool circumstellar envelope (CSE), which fosters a rich gas-phase chemistry (e.g., Duari et al. 1999). IK Tau is relatively nearby, at a distance of $\sim$265 pc (Hale et al. 1997). Estimates of its mass-loss rates range from $3.8 \times 10^{-9}$ to $3 \times 10^{-7}$ $M_\odot$/yr (González Delgado et al. 2003). IK Tau’s proximity and relatively high mass-loss rate facilitate the observation of molecular fingerprints in the frequency ranges of 480–1150 GHz and 1410–1910 GHz at a spectral resolution up to 125 kHz. Single-point observations towards IK Tau were carried out with the Herschel/HIFI instrument in the dual beam switch (DBS) mode with a 3$^\prime$ chop throw. The observation strategy and data-reduction are discussed in Appendix A and in Bujarrabal et al. (2010).

3. Results
In the 13 single-point observations obtained so far, covering a frequency range of 92.8 GHz in total, 31 molecular emission lines have been detected belonging to $^{12}$CO, $^{13}$CO, H$_2^{16}$O, H$_2^{17}$O, H$_2^{18}$O, 28SiO, 29SiO, 30SiO, HCN, SO, and NH$_3$ (see Table A.2 in the Appendix). The detection of NH$_3$ is described in Menten et al. (2010).

For the first time, different excitation lines of water are discovered for the two nuclear spin isomers, ortho- and para-H$_2$O, as well as for the rare isotopologues H$_2^{17}$O and H$_2^{18}$O (see Fig. 1). The observations of these transitions provide information about the total water content, the ortho-to-para ratio, and the isotopic ratios H$_2^{16}$O/H$_2^{17}$O and H$_2^{16}$O/H$_2^{18}$O (see Sect. 3.1). High-excitation rotational transitions are observed for different molecules (see Fig. 2). From the observed line widths, which range between 11 and 19 km s$^{-1}$, it is immediately clear that the HIFI observations offer us a strong diagnostic to trace the wind acceleration zone in the inner envelope (see Sect. 3.2). Moreover, the high-excitation $^{12}$CO $J$ = 10–9 and $J$ = 16–15 lines, complemented with ground-based observations of $^{12}$CO for $J$ = 1–0 to $J$ = 7–6, can be used as temperature indicator for the envelope as close as $\sim$20 $R_*$ (see Sect. 3.2).
3.1. Water in IK Tau’s envelope

Water content: We observed both ortho and para-water lines for different isotopologs in IK Tau (Fig. 1). Using the analytical formula from Groenewegen (1994), we calculated a photodissociation radius of 2.8 \times 10^{16} \text{ cm} or 1870 R_\star, while the theoretical models by Willacy & Millar (1997) predict a value around 1600 R_\star. Assuming the same photodissociation radius for all isotopologs and isomers, we deduced (see Appendix B) a water-abundance [ortho-H_{2}^{16}O/H_2] = 5 \times 10^{-3} and an ortho-to-para water ratio (OPR) of 3:1. Taking the uncertainty in the photodissociation radius into account, the estimated uncertainty in the water abundance is a factor 2 for the assumed envelope structure (see Sect. 3.2).

The total (ortho+para) H_{2}^{16}O abundance for IK Tau derived in this Letter, relative to the total hydrogen content and assuming that all hydrogen is in the form of molecular hydrogen, is [H_{2}^{16}O/H_{tot}] = 3.3 \times 10^{-5}, slightly lower than the photospheric thermodynamic equilibrium (TE) prediction of 7 \times 10^{-5} for an evolved star with a C/O ratio of 0.75 (Cherchneff 2006). The theoretical TE value for the total water abundance is, however, very dependent on the exact value of the C/O ratio, which is unknown for IK Tau. Cherchneff (2006) predicts a higher inner wind abundance of 3.5 \times 10^{-4} around 5 R_\star in the case of pulsationally induced non-equilibrium chemistry. The upper limit implied by the cosmic abundances of carbon and oxygen is no more than 1 \times 10^{-3}, assuming that all carbon is locked in CO and the remaining oxygen goes into H_2O (Anders & Grevesse 1989). Vaporization of icy bodies (Justtanont et al. 2005) or grain surface reactions via Fischer-Tropsch catalysis (Willacy 2004) will also result in a higher water abundance. Considering the agreement between the derived and the TE abundance, the effects of the other processes seem negligible for IK Tau.

On the basis of ISO-LWS data, Maercker et al. (2008) derived for IK Tau an ortho-H_{2}^{16}O abundance (relative to H_2) of 3.5 \times 10^{-4}, significantly higher than the value we derived. Both studies used almost equal photodissociation radius. However, Maercker et al. (2008) only included the ground-state for the excitation analysis. As shown by Decin et al. (2010), neglecting the first vibrational state of the bending mode, v_2 = 1, leads to an underprediction of the HIFI transitions here presented. Since the ISO data used in the study of Maercker et al. are saturated, the integrated intensity is insensitive to the exact value of the abundance, which will result in an overprediction of the H_2O-abundance. We also note that the H_2O line profile predictions are quite sensitive to the exact value of the kinetic temperature and the dust radiation field (and wavelength-dependent absorption efficiencies) (Decin et al. 2010), which in part might also explain the difference between the value we derive [ortho-H_{2}^{16}O/H_2] = 5 \times 10^{-3} and the value of Maercker et al. (2008) [ortho-H_{2}^{16}O/H_2]=3.5 \times 10^{-4}. A comparison with the ISO-LWS data will be presented in Decin et al. (in prep.).

For the oxygen-rich Mira W Hya, Zubko & Elitzur (2000) derived an OPR value of 1:1.3 and Barlow et al. (1996) reported a value of 1:1. However, Barlow et al. noted that their derived value is quite uncertain, due to the high opacities in the water lines used. Justtanont et al. (2010) derived an OPR of 2:1 for the S-type AGB χ Cyg. Our study here is the first time that the OPR value in an oxygen-rich Mira is determined from a combination of emission lines of H_{2}^{16}O, H_{2}^{17}O, and H_{2}^{18}O. The advantage of using the rarer isotopologs is that the opacity of the lines is lower, making the line intensities more sensitive to the OPR value. The observed para-water lines are consistent with an OPR value of 3:1 (+0.4). The lowest energy level of para-H_2O is ~34 K below that of ortho-H_2O. When water forms in the gas phase via exothermic reactions the energy released is much greater than this energy difference and the OPR reflects the high-temperature (~50 K) thermodynamic 3:1 ratio of the statistical weights between the species. The derived OPR value of 3:1 confirms that water in IK Tau is formed in warm and dense regions of the envelope where the chemistry is in thermodynamical equilibrium.

Isotope ratios: Assuming the same photodissociation radius as for the main isotopolog, the isotopic ratios we derive for IK Tau are H_{2}^{16}O/H_{2}^{18}O = 600 (±150) and H_{2}^{17}O/H_{2}^{18}O = 200 (±50), hence well below the solar values (16O/18O = 2632 and 17O/18O = 499; Asplund et al. 2009). Interpreting the derived isotopic ratios in terms of nucleosynthesis and subsequent dredge-ups or extra mixing processes is quite complex (e.g. Harris et al. 1985, 1987; Karakas et al. 2010). In stars that are sufficiently massive to undergo CNO-cycle hydrogen burning, the low initial 17O abundance (assumed to be solar) is enhanced. When helium burning begins inside the hydrogen-burning shell, 17O is expected to be completely destroyed in the region where maximum hydrogen burning occurs. The isotope 18O, on the other hand, is expected to be destroyed during hydrogen burning, so that it virtually disappears from the hydrogen-burning zone and from the hydrogen-exhausted CNO equilibrium zone within it. When helium burning starts, the 18O abundance might slightly increase. A succession of convective mixings brings to the surface material that is affected by these nuclear transformations. Calculations by Harris et al. (1985) show that in every star that becomes a red giant star (M ⋾ 0.8 M_⊙), the initial 16O/17O ratio decreases to ~440 during the first dredge-up, while the 16O/18O slightly increases. The second dredge-up occurs at the end of core helium burning only for the most massive intermediate-mass stars (M ⋾ 4.5 M_⊙). The estimated
The 16O/17O ratio ranges between 150 and 500, while the 16O/18O ratio slightly increases. The third dredge-up occurs in the subsequent helium shell-burning phase for stars ≥2 M⊙, and is expected to yield isotopic ratios of 16O/17O ≤ 200. If hot bottom burning occurs (for stars above 3–4 M⊙), the 16O/17O ratio will be of the order of 20–50. That the 16O/16O ratio is around 600, implies that the first but no subsequent dredge-ups occurred and constrains the initial mass of IK Tau to be within 1–2 M⊙. Alternatively, if the star is more massive than 2 M⊙ and the third dredge-up has occurred (but has not turned the star into a carbon-rich star), transferred material from a post-third dredge-up envelope must have had a 16O/17O ratio ≤ 200. This implies that in stars with 16O/17O ~ 600 the transferred material has been heavily diluted by material from the star’s own envelope with much higher 16O/17O ratios. From Fig. 5 of Harris et al. (1987), it is estimated that IK Tau has a low s-process neutron exposure, τ0 ≤ 0.1, implying a low absolute enhancement of the s-process elements and only a few third dredge-up events, consistent with IK Tau still being an oxygen-rich AGB star.

Hitherto, the lower than solar 16O/18O ratios cannot be explained by any stellar evolution model in the literature. However, IK Tau is not the only Galactic star with a low 16O/18O ratio (see Fig. 3 in Karakas et al. 2010); some barium stars analyzed by Harris et al. (1985) also have a low 16O/18O value. It is anticipated that the observations of other evolved stars in the framework of the HIFISTARS programme (P.I. V. Bujarrabal) will add new information to this discussion.

### 3.2. Thermodynamical structure of the envelope

Being a simple diatomic molecule with a well-understood energy diagram, CO has been successfully used to study the structure of the CSEs around evolved stars (e.g., Schöier et al. 2002; Decin et al. 2006). Different transitions can be used to investigate different regions of the envelope, probing the density, the temperature, and the velocity of the CSE. Decin et al. (2010) used the 12CO J = 1–0 to J = 7–6 lines to determine the thermophysical structure of the CSE of IK Tau beyond ~100 R⋆, based on a non-local thermodynamic equilibrium (non-LTE) radiative transfer analysis of the available transitions. In the first instance, the kinetic temperature and velocity structure of the envelope were calculated by solving the equations of motion of gas and dust and the energy balance simultaneously. To get insight into the structure in the inner wind region, the HCN J = 3–2 and J = 4–3 transitions were used, since observational evidence exists that HCN is formed close to the star (≤3.85'', Marvel 2005).

The Gaussian HCN line profiles indeed point toward line formation partially in the inner wind where the stellar wind has not yet reached its full terminal velocity (Bujarrabal & Alcolea 1991). The results of Decin et al. (2010) infer a wind acceleration that is lower than derived from solving the momentum equation.

#### 3.2.1. Temperature structure

Adopting the thermodynamic structure derived in Decin et al. (2010) (and reproduced in Fig. B.1 of the Appendix), the theoretical line profiles for the 12CO J = 10–9 and J = 16–15 are calculated (see Fig. 2) using the non-LTE radiative transfer code GASTRoNoOM (Decin et al. 2006, 2010). The 12CO J = 10–9 line is very well reproduced, while the J = 16–15 line exhibits slightly larger deviations. The latter most likely reflects the very difficult calibration of this frequency setting (for which standing waves heavily perturbed the baseline, see Bujarrabal et al. 2010). This result is consistent with the temperature structure in the region between 20 and 100 R⋆ derived by Decin et al. (2010).

#### 3.2.2. Velocity structure

To constrain the wind acceleration in the CSE, all molecular emission lines as shown in Figs. 1–2 were modelled (see Appendix B). The line formation region of each molecular line was estimated by considering the range of projected radii where Iν(p) ∝ p dν, with Iν the intensity at the line center and p the impact parameter, exceeds half of its maximum value (see Fig. 3). We note that the radial extent of the line formation region is almost insensitive to the exact value of the velocity structure. Optical depths effects can strongly affect the observed line widths, and detailed radiative transfer modelling (as presented in this Letter) is required to determine the underlying velocity structure. Most of the observed lines have line widths in excess of 17 km s⁻¹. However, a few lines are considerably narrower,
and their line formation regions are located in that part of the envelope where the wind has not yet reached its terminal velocity (19 km s$^{-1}$). Although the line formation regions are quite broad, we find the first observational evidence that the wind acceleration is slower than implied by the momentum equation, corroborating the results of Decin et al. (2010). Using the classical $\beta$-parametrization (e.g., Lamers & Cassinelli 1999) to simulate the velocity structure,

$$v(r) \approx v_0 + (v_{\infty} - v_0) \left(1 - \frac{R_{\text{d}}}{r}\right)^{2/\beta},$$

(1)

where $v_0$ is the velocity at the dust condensation radius and $v_{\infty}$ is the terminal velocity, we find that $1 \leq \beta \leq 2$. The theoretical line predictions shown in this Letter are computed for $\beta = 1$. The momentum equation, in contrast, matches a much steeper velocity profile with $\beta = 1.5$ is shown with the red dotted line. The vertical dashed black line indicates the dust condensation radius $R_{\text{d}}$. The velocity at $R_{\text{d}}$ is assumed to be equal to the local sound velocity.

**Fig. 3.** Velocity profile of IK Tau. Velocity data are obtained from mapping of maser emission: SiO (Boboltz & Diamond 2005), H$_2$O (Bains et al. 2003), and OH (Bowers et al. 1989). The CO expansion velocity derived from ground-based CO $J = 1$–$0$ data is also indicated (Decin et al. 2010). The triangles show the place in the envelope where the line formation is highest for the HIFI data presented in Figs. 1–2, i.e., where $I_{12}(p)p^2$ is at its maximum. The horizontal bars show the minimum and maximum radial distance for the line formation of each individual transition. The vertical bars show the uncertainty on the observed line widths. The expansion velocity deduced from solving the momentum equation is shown by the full green line. The dashed blue line represents a power law (Eq. (1)) with $\beta = 1$ (as used for the modelling in Appendix B). For comparison, an even smoother expansion velocity structure with $\beta = 1.5$ is shown with the red dotted line. The vertical dashed black line indicates the dust condensation radius $R_{\text{d}}$. The velocity at $R_{\text{d}}$ is assumed to be equal to the local sound velocity.

4. Conclusions

Using the HIFI spectrometer onboard Herschel, we have observed the evolved oxygen-rich Mira star, IK Tau, in 31 molecular emission lines. For the first time, several lines of ortho and para H$_2$O, and the rarer isotoplogs H$_2$O and H$_4$O have been detected. We have deduced a total water content (relative to H$_2$) of $6.6 \times 10^{25}$, and an ortho-to-para ratio of 3:1. The measured thermal emission from water therefore points toward TE chemistry, as opposed to pulsationally induced non-equilibrium chemistry, grain surface reactions, or evaporation of icy bodies. For the isotopic ratios, we find subsolar values H$_2$O/H$_2$O = 0.600 and H$_2^18$O/H$_2$O = 200.

The high-excitation lines of $^{12}$CO, $^{13}$CO, $^{28}$SiO, $^{29}$SiO, $^{30}$SiO, HCN, and SO indicate that the wind acceleration is slower than hitherto anticipated from solving the momentum equation. These results show the great capability of HIFI to study the complex thermodynamical and chemical envelopes of evolved stars in tremendous detail.

The real DBS mode was used for bands 1 up to 5, while FastDBS was applied to bands 6 and 7 to achieve higher stability with respect to electrical standing waves. Two orthogonal polarizations were measured simultaneously. The double-sideband (DSB, Helmicch et al., in prep.) observations ensure an instantaneous 8 GHz and 5.2 GHz frequency coverage by the wide band spectrometer (WBS) for respectively bands 1 up to 5, and bands 6 and 7. The spectral resolution is 0.5 MHz. Care was taken in choosing local oscillator (LO) frequencies such that no strong spurious signals, baseline removal, stitching of the spectrometer subbands, and averaging, was performed in CLASS. When the quality of the spectra measured in both horizontal and vertical subbands, and averaging, was performed in CLASS. When the quality of the spectra measured in both horizontal and vertical subbands, and averaging, was performed in CLASS. When the quality of the spectra measured in both horizontal and vertical subbands, and averaging, was performed in CLASS. When the quality of the spectra measured in both horizontal and vertical subbands, and averaging, was performed in CLASS.

All data presented in this Letter were converted from the antenna-temperature (TΛ) scale to the main-beam temperature (TMB) scale according to $T_{\text{MB}} = T_{\Lambda} / \eta_{\text{MB}}$, with values of the main-beam efficiency ηMB (Table A.1) calculated for the LO frequency νLO, according to

$$\eta_{\text{MB}} = \eta_B \times \exp \left( - \frac{(\nu_{\text{LO}}/\text{GHz})^2}{6 \times 10^7} \right) \times \eta_F,$$

(A.1)

with $\eta_B = 0.72$ and $\eta_F = 0.96$ being the beam efficiency in the 0 Hz frequency limit and the forward efficiency, respectively. The absolute calibration accuracy ranges from 10% for the lowest frequency lines up to 30% for the high frequency (>1 THz) lines.

Appendix B: Radiative transfer modelling

The molecular emission lines shown in Figs. 1–2, were modelled using the non-LTE radiative transfer code GASTRoNOoM (Decin et al. 2006). Last updates to the code and a discussion of the available line lists and collisional rates can be found in Decin et al. (2010). The thermodynamical structure (see Fig. B.1) determined by Decin et al. (2010) was confirmed using the new HIFI observations (Sect. 3.2). Modelling the CO and H2O lines provides insight into to the cooling/heating rates by transitions of these molecules (see also Decin et al. 2006, 2010). As can be seen in Fig. B.3, H2O transitions provide the main cooling agent in the region up to $\sim 2 \times 10^{15}$ cm, while adiabatic cooling takes over for the region beyond $\sim 2 \times 10^{15}$ cm.

In the first instance, the molecular abundance stratifications derived by Decin et al. (2010) were assumed to model the 13CO, 28SiO, 29SiO, 30SiO, HCN, and SO lines (see full black lines in Fig. 2 and full lines in Fig. B.2). Using the new HIFI observations, the 13CO and 28SiO abundance fractions were refined in the inner envelope (see dashed black lines in Fig. 2 and dashed lines in Fig. B.2).

The radiative transfer modelling for water included the 45 lowest levels of the ground state and first vibrational state (i.e. the bending mode $v_2 = 1$ at 6.3 μm) for all isotopologs. Level energies, frequencies, and Einstein A coefficients were extracted from the HITRAN water line list (Rothman et al. 2009). The H2O-H2 collisional rates were taken from Faure et al. (2007). The effect of including excitation to the first excited vibrational state of the asymmetric stretching mode ($v_3 = 1$) was tested, and was found to be negligible (Decin et al. 2010).

A good agreement was found for the HCN(7–6) line proving that the inner abundance fraction [HCN/H2O] is $\sim 2.2 \times 10^{-7}$. The 12CO J = 9–8 and J = 10–9 lines are somewhat underpredicted assuming a 12CO/13CO ratio of 14 as obtained by Decin et al. (2010). Decreasing this ratio to 7 yields a better fit, but we
Thermodynamic structure of the envelope of IK Tau derived from the $^{12}$CO $J = 1-0$ to $J = 7-6$ and HCN $J = 3-2$ and $J = 4-3$ rotational line transitions for the stellar parameters given in Table B.1 (Decin et al. 2010). The start of the dusty envelope, $R_{\text{inner}}$, is indicated by the dotted line.

Notes. $T_{\text{eff}}$ is the effective stellar temperature, $R_\star$ denotes the stellar radius, $M$ the gas mass-loss rate, $R_{\text{inner}}$ the dust condensation radius, $v_\infty$ the terminal velocity of the wind, and $v_{\text{turb}}$ the turbulent velocity in the wind. The molecular fractional abundances are given relative to $H_{\text{tot}} = n(H) + 2n(H_2)$, and denote the abundance at the dust condensation radius (see Fig. B.2). Values between parentheses denote refined inner wind abundance values obtained from the new HIFI observations. The fractional abundances for all water isotopologs and isomers are based on the HIFI data presented in this Letter.

point out that the line profiles are quite noisy. The $^{13}$CO fractional abundance was obtained assuming the same photodissociation radius as for $^{12}$CO (Mamon et al. 1988). However, if the effect of less self-shielding of $^{13}$CO (compared to $^{12}$CO) were more important than estimated by Mamon et al. (1988), the photodissociation radius of $^{13}$CO would be smaller, affecting the low excitation rotational transitions more than the higher excitation lines observed by HIFI. Another possibility might be that the velocity structure is steeper than the $\beta = 1$ power law now assumed in the region between $\sim 20$ and $150 R_\star$, where these high-excitation lines are mainly formed. Since a constant mass-loss rate is assumed, this would imply a lower density in this region, and hence a higher $^{13}$CO abundance fraction to produce the correct line intensity.

Only one higher-excitation $^{28}$SiO line has been observed so far. The $J = 14-13$ transition indicates that the inner wind abundance might be a factor 2 lower than deduced by Decin et al. (2010), yielding an inner wind abundance of $4 \times 10^{-6}$, decreasing to $2 \times 10^{-7}$ around $180 R_\star$. The isoplotopolog line of $^{29}$SiO ($13-12$) is well predicted for an inner abundance of $3 \times 10^{-7}$; the higher excitation $J = 26-25$ line of both $^{29}$SiO and $^{30}$SiO are consistent with the HIFI observations. This implies an isotopic ratio of $^{28}$SiO/$^{29}$SiO of 13.

Using the abundance pattern determined by Decin et al. (2010), the SO($13_{14} - 12_{13}$) is quite well predicted.
