ABSTRACT

Herschel/HIFI observations of water from the intermediate mass protostar NGC 7129 FIRS 2 provide a powerful diagnostic of the physical conditions in this star formation environment. Six spectral settings, covering four H₂¹⁶O and two H₂¹⁸O lines, were observed and all but one H₂¹⁸O line were detected. The four H₂¹⁶O lines discussed here share a similar morphology: a narrower, ≈ 6 km s⁻¹, component centered slightly redward of the systemic velocity of NGC 7129 FIRS 2 and a much broader, ≈ 25 km s⁻¹ component centered blueward and likely associated with powerful outflows. The narrower components are consistent with emission from water arising in the envelope around the intermediate mass protostar, and the abundance of H₂O is constrained to $\approx 10^{-7}$ for the outer envelope. Additionally, the presence of a narrow self-absorption component for the lowest energy lines is likely due to self-absorption from colder water in the outer envelope. The broader component, where the H₂O/CO relative abundance is found to be ≈ 0.2 , appears to be tracing the same energetic region that produces strong CO emission at high *J*.

Key words. astrochemistry – stars: formation

1. Introduction

Observations of star formation in nearby molecular clouds have provided a reasonably clear picture of this process for low-mass stars. Nevertheless fundamental questions remain. One of these is the variation in the formation process between low through high mass stars. The intermediate mass (IM) sub-program within the Water In Star-forming regions with *Herschel* (WISH) key program (van Dishoeck et al., in prep.) aims to use observations of water, and complementary molecules, to probe the regions around several intermediate mass protostars – focusing on the structure of the envelope and the energetics of the outflow. These sources are usually defined as young stellar objects (YSOs) with bolometric luminosities between $75 L_{\odot}$ and $2 \times 10^3 L_{\odot}$. A key goal for the longer term of this investigation is to place IM star formation in context with its low- and high-mass brethren.

An excellent example of an extremely young IM protostar is NGC 7129 FIRS 2 (Eiroa et al. 1998; Fuente et al. 2001, 2005), located at a distance of 1260 ± 50 pc from the Sun

(Shevchenko & Yakubov 1989). With a luminosity of $500 L_{\odot}$ and estimated stellar mass of $5 M_{\odot}$, FIRS 2 lies near the middle of the IM luminosity range. The protostar has produced a hot core (Fuente et al. 2005) but has no evidence for a large, well-developed disk – implying it is a young source. A powerful quadrupolar outflow, likely due to the superposition of two bipolar jets, is found very close to this source (Fuente et al. 2001).

NGC 7129 FIRS 2 has been the subject of significant investigation over the last year. A robust model for the enshrouding, and pre-natal, envelope has been proposed by Crimier et al. (2010) utilizing all available far infrared (*Spitzer*) and submillimeter (JCMT, IRAM) brightness measurements. Additionally, Fich et al. (2010) used *Herschel* PACS observations of highly energetic CO (up to CO *J* = 33–32 which arises from a level at an energy equivalent 3093 K) to analyse the energetics associated with NGC 7129 FIRS 2. They found that these CO lines are much brighter than expected from the envelope alone, revealing the need for additional heating beyond simple reprocessing of the protostellar radiation. A warm slab model with temperatures greater than 1000 K, considered a proxy for shock heating in or along the surfaces of the outflow lobes, provided a much better fit to the CO observations. A lack of spectral resolution in the PACS data hindered further investigation into the connection between the CO lines and the outflow.

* *Herschel* is an ESA space observatory with science instruments provided by European-led Principal Investigator consortia and with important participation from NASA.

			CO 10-9 ^a	10-9	1151.99

Notes. ^(a) Only a preliminary reduction of this observation has been performed, it is discussed only in Sect. 3.2.

In this paper we present a first-look at the water spectra obtained toward NGC 7129 FIRS 2 with the HIFI instrument (de Graauw et al. 2010) on the *Herschel* Space Observatory (Pilbratt et al. 2010). The wealth of spectrally resolved water lines observed provide powerful diagnostic measures for the envelope and the outflow.

2. Observations

Herschel HIFI was used to obtain data for this project during the *Herschel* science demonstration phase and the HIFI priority science program, from 3–20 March, 2010. The observations were taken using the fast dual-beam switch mode with a standard nod of 3' using receiver bands 1, 2, and 4. In total six spectral settings were selected, covering four H₂¹⁶O transitions and two H₂¹⁸O transitions, with integration times between 15 min and 1 h. Two isotopologue lines of CO were also located within these settings. CO 10–9 was also observed on June 15, 2010, with a 10 min integration in band 5 using the fast dual-beam switch mode. The complete set of observed lines are shown in Table 1. All the observations were taken toward NGC 7129 FIRS2, at 21^h43^m1.7^s 66° 03' 23" (J2000). Diffraction-limited beamsizes range from 20''–40'' (equivalent to 25 000–50 000 AU at the distance of NGC 7129).

The data were pipelined using HIPE 3.0¹ (Ott 2010) and the data analysis was completed using both HIPE 3.0 and CLASS. The results of the two analyses were found to be the same to better than twenty percent, where the largest uncertainties were found during the fitting of multiple components. Before the reduction, the chop positions were differenced to check for extended emission and none was detected. During the reduction, the H and V polarizations were compared to assess quality and then averaged. In most cases the two polarizations showed no significant variations. The H₂¹⁶O 3₁₂–3₀₃ line, however, showed both a lower peak intensity and line width for the V polarization, resulting in an 8% difference in integrated intensity. For both polarizations, the overall morphology of the spectrum is similar, with the variation likely due to the extended nature of the source and slight offsets in the H and V beam positions. Finally, the WBS and HRS spectra were compared for consistency. Regions containing spurs were excluded from the analysis and a first order polynomial baseline was removed from each spectrum. The WBS data were ultimately smoothed to the goal resolution of 1.1 MHz and the antenna temperature T_A^* was converted to T_{mb} by applying a main beam efficiency of 0.74.

The four H₂¹⁶O transitions were observed and are shown in Fig. 1. The spectra show evidence for at least two components: a narrower line peaked slightly redward of the systemic velocity of the source (–9.8 km s^{–1}) and a broad line blue-shifted from the

Table 2. Water and CO line emission toward NGC 7129 FIRS 2.

Transition	Component	rms ^a (mK)	$T_{MB}^{peak,b}$ (K)	$\int T_{MB} dv^b$ (K km s ^{–1})	V_{LSR}^c (km s ^{–1})	$FWHM^d$ (km s ^{–1})	
H ₂ ¹⁶ O 1 ₁₁ -0 ₀₀	no Gaussian fit	16	0.59	8.4	–8.2		
	2 ₀₂ -1 ₁₁	narrow	20	0.36	2.3	–7.2	6.2
		broad	20	0.23	6.1	–12.4	24.6
	2 ₁₁ -2 ₀₂	narrow	16	0.21	1.5	–7.5	6.5
broad		16	0.11	3.1	–13.7	26.8	
3 ₁₂ -3 ₀₃	narrow	16	0.14	1.7	–7.3	7.8	
	broad	16	0.11	2.8	–14.5	24.4	
H ₂ ¹⁸ O 1 ₁₀ -1 ₀₁		5	0.015	0.071	–8.5	5.3	
H ₂ ¹⁸ O 2 ₀₂ -1 ₁₁	not seen	5		<0.010 ^e			
C ¹⁸ O 5-4		5	0.16	0.49	–9.8	2.1	
¹³ CO 10-9		20	0.13	0.44	–9.8	5.5	

Notes. ^(a) The rms measure is taken over a 1 km s^{–1} range.

^(b) Uncertainties in the peak temperature and integrated line intensity are dominated by calibration issues. For H₂¹⁶O 1₁₁-0₀₀, 2₀₂-1₁₁, 3₁₂-3₀₃, and ¹³CO 10–9 the uncertainty is 32%. For all other lines the uncertainty is 16%.

^(c) Velocity accuracy better than ~0.5 km s^{–1}.

^(d) A 20% uncertainty in the line widths is due primarily to the component separation.

^(e) The 3 σ detection limit, for data smoothed to the expected line width (5 km s^{–1}), is 0.015 K.

Fig. 1. H₂O spectra detected toward NGC 7129 FIRS 2 with HIFI. Note the similarities in morphology between the lines, especially the appearance of at least two emission components, narrow and broad (see Fig. 3). The lowest energy transition lines also show evidence for somewhat blue-shifted self-absorption.

systemic velocity. The ground-state transition shows significant self-absorption, with a minimum at –10.4 km s^{–1}, hints of which can be seen in the other observed transitions, and is likely due to colder water lying along the line of sight toward NGC 7129 FIRS 2, with the most likely source of absorption being the protostellar envelope. Two CO isotopologues were also detected (see Fig. 2). While both these lines peak at the systemic velocity and are much narrower than the H₂¹⁶O lines, the ¹³CO 10–9 line is broader than the C¹⁸O 5–4 line (see Table 2). Of the water isotopologues, only the H₂¹⁸O 1₁₀-1₀₁ line was sufficiently strong to be unambiguously detected (Fig. 2).

3. Discussion

The H₂¹⁶O lines detected toward NGC 7129 FIRS 2 provide an opportunity to examine the physical and chemical environment of this young IM protostar. Attempts to fit the spectra with two

¹ HIPE is a joint development by the *Herschel* Science Ground Segment Consortium, consisting of ESA, the NASA *Herschel* Science Center, and the HIFI, PACS and SPIRE consortia.

Fig. 2. Isotopologue CO and water spectra observed toward NGC 7129 FIRS 2 with HIFI. Note the width of the isotopologues relative to the main line.

Fig. 3. Spectrum of the $\text{H}_2^{16}\text{O } 2_{02}-1_{11}$ transition (blue) superposed with the two Gaussian fit (black) from Table 2. The fit includes a narrow, 6.2 km s^{-1} FWHM, component centered at -7.2 km s^{-1} (grey) and a much broader, 24.6 km s^{-1} FWHM component, shifted slightly blueward at -12.4 km s^{-1} (purple).

Gaussian components proved reasonably successful for the excited lines (Table 2 and Fig. 3). For these three lines, the narrower component was well described by a $\approx 6 \text{ km s}^{-1}$, Gaussian centered redward of the systemic velocity of the source near -7 km s^{-1} coupled with a broader, 25 km s^{-1} , Gaussian centered near -13.5 km s^{-1} (Figs. 1 and 3). The likely additional absorption component in each of these spectra could account for the small variations in the line centroids and widths of the fits. Similar profiles are seen for low- (Kristensen et al. 2010) and high-mass (Chavarría et al. 2010) protostars, where they are named medium and broad components. Even narrower lines, $\approx 1-2 \text{ km s}^{-1}$ FWHM, are seen in self-absorption of the lowest-energy water lines as well as in ground-based emission lines such as CS 3–2. The latter profile also reveals a 6 km s^{-1} component (Fuente et al. 2005).

Beyond the morphological nature of these lines, it is possible to compare the water emission against model predictions. Fich et al. (2010) note that NGC 7129 FIRS 2 has two main components which may account for the observed emission. The

prenatal envelope, which is warmed by the IM protostar embedded within it, may produce water emission. Also, the source powers an energetic outflow which could produce water emission either in the outflow itself or along the shock heated walls, where the outflow interacts with the denser envelope. In the following subsections, we consider the water emission from each of these components and compare the expectations against the HIFI observations.

3.1. Water from a spherical protostellar envelope

The spherical envelope model for NGC 7129 FIRS 2 computed by Crimier et al. (2010) fits the spectral energy distribution from the far infrared through the submillimeter very well and thus provides a reasonable set of physical conditions for examining the observed water emission. This model has an envelope mass of $50 M_{\odot}$, an optical depth at $100 \mu\text{m}$ of 2.3, an inner radius of 100 AU and an outer radius of 18 600 AU. The temperature at the inner envelope radius is 289 K, falling to 100 K at a radius of 373 AU where the H_2 density is $4.4 \times 10^7 \text{ cm}^{-3}$. The density varies as a power-law with index -1.4 .

Model water lines were calculated using the RATRAN code (Hogerheijde & van der Tak 2000) using collisional cross sections for $\text{H}_2\text{O}-\text{He}$ from Green (1993), scaled by 1.348 to make a first order approximation for collisions with H_2 . An ortho-to-para ratio of 3 was assumed for H_2 . The density and temperature profile of the Crimier et al. (2010) model were followed and the radial velocity profile was assumed to be the free-fall velocity appropriate to a central object of mass $1.1 M_{\odot}$ (ie. velocity of -4.2 km s^{-1} at the inner radius and -0.31 km s^{-1} at the outer edge). Models were calculated for two abundance zones in the envelope: a warm, $>100 \text{ K}$ inner envelope with a higher abundance and a cooler outer envelope with a lower abundance, perhaps characteristic of a “freeze-out” zone.

As a starting point, we modelled the ortho- $\text{H}_2^{18}\text{O } 1_{10}-1_{01}$ observation. This line has a similar profile to the narrower components of the H_2O lines and if it can be reproduced by the spherical envelope model we may conclude that the narrower component of the H_2O lines also are likely to arise in the envelope. A large number of models were run over a range of inner ($10^{-9}-10^{-4}$) and outer ($10^{-7}-3 \times 10^{-11}$) envelope abundances. The non-thermal velocity width parameter b was also varied and values $\geq 3 \text{ km s}^{-1}$ were strongly ruled out, while $b = 1 \text{ km s}^{-1}$ produced too narrow a line. The best fit was found for $b = 2 \text{ km s}^{-1}$.

The abundance of ortho- H_2^{18}O in the outer envelope is well-constrained to be $3 \pm 1 \times 10^{-10}$, while inner envelope abundances between 3×10^{-7} and 1×10^{-5} produce results consistent with the integrated flux of the ortho- $\text{H}_2^{18}\text{O } 1_{10}-1_{01}$ line (Table A.1). These are surprisingly high values; indeed, the top end of this range is impossible when the cosmic ^{18}O abundance is considered. The para- $\text{H}_2^{18}\text{O } 2_{02}-1_{11}$ was modeled in a similar way. The non-detection of this line constrains the outer envelope abundance of para- H_2^{18}O to $\leq 3 \times 10^{-11}$. The model fits are insensitive to the inner envelope abundance used (Table A.2) and this may be a consequence of beam dilution.

Assuming that the ratio of $^{16}\text{O}/^{18}\text{O} = 550$ is also representative of the ratios of both of the ortho and para $\text{H}_2\text{O}/\text{H}_2^{18}\text{O}$, we examined models for the narrower components of the H_2O lines with outer envelope abundances near 1×10^{-7} and inner abundances up to 3×10^{-4} (limited by the cosmic O abundance). The best fitting models indicate that the outer envelope abundance of total H_2O is of order a few 10^{-7} , and are summarised in Table 3. The ortho to para ratio implied by the best fit outer envelope

Table 3. Overview of best fitting spherical envelope models.

Isotopologue	Outer abundance ^a	Comment
o-H ₂ ¹⁸ O	$3 \pm 1 \times 10^{-10}$	implies o-H ₂ O $1.7 \pm 0.5 \times 10^{-7b}$
p-H ₂ ¹⁸ O	$\leq 3 \times 10^{-11}$	implies p-H ₂ O 1.7×10^{-8b}
o-H ₂ O	3×10^{-7}	Well constrained by both excited para lines
p-H ₂ O	3×10^{-8}	$\geq 10^{-8}$ required for self-absorption

Notes. ^(a) The relative abundance of species listed, and not total H₂O

^(b) Assuming $^{16}\text{O}/^{18}\text{O} = 550$.

abundances is 10:1, this is highly unlikely and within the calibration ($\leq 32\%$) and model uncertainties the ratio is consistent with 3. The abundance of the inner envelope could not be constrained and the observed line profiles were poorly reproduced, particularly in the case of the para lines. Whilst the parameter space of the models are still not fully explored, this suggests limitations in the model used with the assumptions concerning the velocity field and spherical structure most suspect.

3.2. Water from a slab model

Fich et al. (2010) concluded that the energetic PACS CO lines observed toward NGC 7129 FIRS 2 could not be fit by a re-processing spherical envelope model as there was an insufficient volume of warm gas to produce the strong emission observed. It was postulated that the CO emission might arise along shock heated walls in the outflow cavity, where the gas temperature can reach extreme values. NGC 7129 FIRS 2 is known to contain a powerful outflow (Fuente et al. 2001) and observations of low-mass stars have shown that such outflows can produce heated walls via UV photons (van Kempen et al. 2009) and shocks (Giannini et al. 1999; van den Ancker et al. 2000; Nisini et al. 2002; Arce et al. 2007; van Kempen et al. 2010). Fich et al. (2010) used the RADEX code to show that the observed CO emission could be explained within a model of a slab geometry with a temperature of 1100 K, an H₂ density of $1.0 \times 10^8 \text{ cm}^{-3}$, and a CO column density of 10^{14} cm^{-2} . This model constrained the lowest temperature at which the CO observations could be adequately fit. A more comprehensive set of CO models was produced for this paper, and a best fit is found for a temperature of 1200 K, an H₂ density of 10^7 cm^{-3} and a column density of CO of $1.7 \times 10^{14} \text{ cm}^{-2}$. Assuming a CO abundance of 10^{-4} , these results suggest a slab with thickness $dz \sim 10^{10} \text{ cm}$.

Using these same conditions (1200 K and 10^7 cm^{-3}), but substituting water for CO, may provide an additional constraint on the possible shock heating conditions, and the conditions under which the broad component of the water lines arise. The water lines observed with HIFI set the limit on the ortho-H₂O column at $2.3 \pm 0.2 \times 10^{13} \text{ cm}^{-2}$ while the para-H₂O lines observed set a maximum limit in the column at $7.5 \pm 0.5 \times 10^{12} \text{ cm}^{-2}$, giving an ortho-to-para ratio of 3.

These models imply a water abundance that is approximately five times lower than CO and can be compared with that found from analysis of the H₂O and CO line ratios in the line wing, where the emission is optically thin. The CO 10–9 line exhibits a similar profile to that seen in the H₂O lines (Fig. A.1) and be compared directly with the H₂O 2₀₂–1₁₁ line, as they are observed in almost the same beam (22'' vs. 19''). The abundance ratio was calculated with RADEX using a density of 10^6 cm^{-3} . Above $T = 150 \text{ K}$ the results are insensitive to changes in temperature. The abundance ratio is found to be ≈ 0.2 near the line centre and approaches 0.3 at the highest velocities in the red wing (Table A.3). This is consistent with the findings from the slab model and also with the behaviour seen in the low-mass

sources of Kristensen et al. (2010), who report this indicates that $\approx 10\%$ of the available O is in H₂O.

That the same model can be used to fit both the PACS CO observations and the broad component of the HIFI H₂O lines supports the hypothesis that these lines arise along shock heated walls in the outflow cavity. Shock models will allow to better constrain the conditions under which these broad lines arise.

4. Conclusions

Herschel HIFI spectroscopy of water in the vicinity of the intermediate mass protostar NGC 7129 FIRS 2 has revealed that the water emission arises from at least two sources. The observed emission lines can be decomposed into both a narrower, $\approx 6 \text{ km s}^{-1}$, component and a much broader, $\approx 25 \text{ km s}^{-1}$ component. The integrated intensity of the narrower component can be fit by a simple free-falling envelope model with an outer envelope total H₂O abundance of $\approx 10^{-7}$, although the shape of the line profiles are not reproduced. The broader component appears to be related to the heated gas already observed in high-*J* CO lines with PACS and associated with the known energetic outflow. These initial modeling results suggest that a dedicated parameter study for this source should prove extremely fruitful in constraining the physical and chemical conditions in NGC 7129 FIRS 2.

Appendix A:

Table A.1. Summary of o-H₂¹⁸O 1₁₀–1₀₁ model results.

Envelope abundance		$T_{\text{MB}}^{\text{peak}}$	$\int T_{\text{MB}} dv$
Inner	Outer	(K)	(K km s ⁻¹)
1×10^{-5}	3×10^{-10}	0.017	0.071
3×10^{-6}	3×10^{-10}	0.018	0.075
1×10^{-6}	3×10^{-10}	0.017	0.069
3×10^{-7}	3×10^{-10}	0.016	0.065
1×10^{-7}	3×10^{-10}	0.015	0.060
3×10^{-8}	3×10^{-10}	0.014	0.054
1×10^{-8}	3×10^{-10}	0.014	0.050
1×10^{-5}	2×10^{-10}	0.015	0.063
3×10^{-6}	2×10^{-10}	0.014	0.060
1×10^{-6}	2×10^{-10}	0.014	0.060
3×10^{-7}	2×10^{-10}	0.013	0.052
1×10^{-5}	1×10^{-10}	0.010	0.043
1×10^{-6}	1×10^{-10}	0.009	0.038
3×10^{-7}	1×10^{-10}	0.009	0.036
1×10^{-7}	1×10^{-10}	0.008	0.032
3×10^{-8}	1×10^{-10}	0.007	0.027

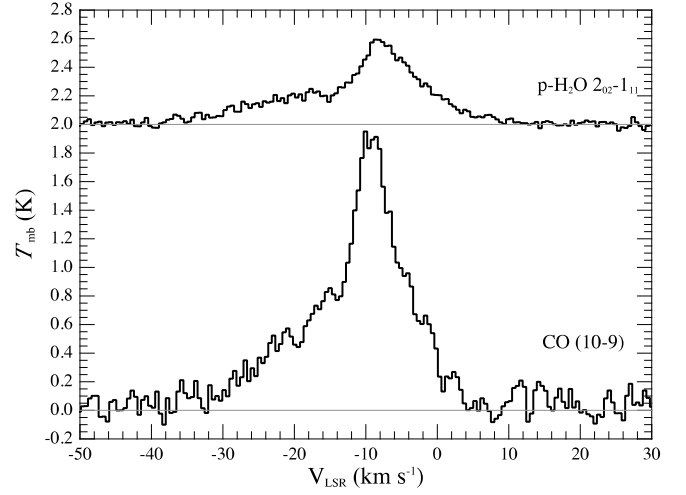

Notes. The observed line has a $T_{\text{MB}}^{\text{peak}} = 0.015$ K and an $\int T_{\text{MB}} dv = 0.071$ K km⁻¹, the best fitting model is selected by comparison with the latter.

Table A.2. Summary of p-H₂¹⁸O 2₀₂–1₁₁ model results, which are compared with $\int T_{\text{MB}} dv \leq 0.010$ K km⁻¹.

Envelope abundance		$T_{\text{MB}}^{\text{peak}}$	$\int T_{\text{MB}} dv$
Inner	Outer	(K)	(K km s ⁻¹)
3×10^{-6}	1×10^{-10}	0.0088	0.033
1×10^{-6}	1×10^{-10}	0.0088	0.033
3×10^{-7}	1×10^{-10}	0.0085	0.032
3×10^{-6}	3×10^{-11}	0.0026	0.0097
1×10^{-6}	3×10^{-11}	0.0027	0.0099
3×10^{-7}	3×10^{-11}	0.0023	0.0085
3×10^{-6}	1×10^{-11}	0.0008	0.0032
1×10^{-6}	1×10^{-11}	0.0008	0.0031
3×10^{-7}	1×10^{-11}	0.0008	0.0030

Table A.3. H₂O 2₀₂–1₁₁/CO 10–9 abundance ratios in 5 km s⁻¹ intervals, calculated from CO 10–9/ H₂O 2₀₂–1₁₁ line ratios, using $n = 10^6$ cm⁻³ and $T > 150$ K.

dv_{LSR}	CO 10–9/ H ₂ O 2 ₀₂ –1 ₁₁	$x(\text{H}_2\text{O})/$ $x(\text{CO})$
–10––5	3.25	0.27
–5–0	3.86	0.22
0–5	4.14	0.21
5–10	1.86	0.47

**Fig. A.1.** The H₂O 2₀₂–1₁₁ and CO 10–9 transitions; the main isotopologue of CO exhibits a profile similar to the main isotopologues of H₂O.
