Lipases and carboxylesterases affect moth sex pheromone compounds involved in interspecific mate recognition

Moth sex pheromones are a classical model for studying sexual selection. Females typically produce a species-specific pheromone blend that attracts males. Revealing the enzymes involved in the interspecific variation in blend composition is key for understanding the evolution of these sexual communication systems. The nature of the enzymes involved in the variation of acetate esters, which are prominent compounds in moth pheromone blends, remains unclear. We identify enzymes involved in acetate degradation using two closely related moth species: *Heliothis (Chloridea) subflexa* and *H. (C.) virescens*, which have different quantities of acetate esters in their sex pheromone. Through comparative transcriptomic analyses and CRISPR/Cas9 knockouts, we show that two lipases and two esterases from *H. virescens* reduce the levels of pheromone acetate esters when expressed in *H. subflexa* females. Together, our results show that lipases and carboxylesterases are involved in tuning Lepidoptera pheromones composition.

One of the most fascinating questions in evolutionary biology is to understand how new species arise. Sexual signals, through which individuals recognize suitable mating partners, can have a critical role in prezygotic isolation of species. As such, sexual signals offer a seductive model to uncover evolutionary patterns that lead to speciation. Identifying genes underlying the production and detection of sexual signals opens a door to the analysis of their evolution across species.

Pheromones are semiochemicals released by a sender that modify the behavior of a conspecific receiver. Sex pheromones are signals used in the context of mate finding or courtship. In most nocturnal moths, females typically produce a species-specific blend of a small number of so-called type I sex pheromone components to which conspecific males are attracted. The species-specificity of moth sex pheromone blends is mainly determined by the ratio of alcohols, aldehydes, and acetate esters (hereafter also referred to as “acetates”) with carbon backbones of various lengths and degrees of desaturation. Since the sex pheromones of more than 2000 moth species have been identified, moths have become exemplary models to understand the evolution of sexual communication. In sympatric, ecologically similar species with similar pheromone blends, females may not only release attractive components, but also repellent pheromone components that prevent attraction of heterospecific males. Such is the case with *Heliothis (Chloridea) subflexa* females, where males of the closely related *H. (C.) virescens* are repelled by the acetate esters in the *H. subflexa* pheromone.

Despite 25 years of research in which techniques of molecular biology have been applied to pheromone biosynthetic enzymes, the genes involved in regulating the proportion of acetates in the blends have not been identified yet. This is surprising, because a phylogenetic survey covering 1572 moth species in 619 genera and 49 families, shows that five different acetates are the most commonly occurring components of moth pheromones. Biochemical studies have shown that microsomal fractions of female pheromone glands of the
spruce budworm *Choristoneura fumiferana* and two other tortricids as well as the crambids *Ostrinia nubilalis* can conjugate a wide variety of fatty alcohols to acetate esters provided by acetyl-CoA through acetyltransferase activity.

Previous attempts to link candidate genes to acetyltransferase activity include a study in which expression differences of candidate acetyltransferase genes failed to correlate with the presence/absence of acetates in the two closely related and sympatrically occurring species *H. virescens* and *H. subflexa*. Also notable is a study in which 34 candidate genes from *Agrotis segetum* failed to yield acetate esters in a yeast expression system. Misleadingly, each of these 34 genes is now annotated as “fatty alcohol acetyltransferase” in GenBank (Accession Numbers KJ579206–KJ579239). This precedent has led to paralogs in other species being named as acetyltransferases, despite the absence of any biochemical evidence (e.g., *Helicoverpa armigera* (Accession Numbers MF706167–MF706196) and *H. assulta* (Accession Numbers MF687638–MF687667). *Antheraea pernyi* (ACT1–ACT22)).

*Heliothis virescens* and *H. subflexa* are two closely related species occurring in sympatry. These noctuid moths have recently been introgressed into the *H. subflexa* genomic background by using backcross females, where no crossing-over takes place. After 9 generations, backcross males were crossed to *H. subflexa* females, which resulted in just one end of *HviChr20* segregating in DD23 (Supplementary Fig. S1). This partial *HviChr20* introgression significantly reduced acetate levels in the female sex pheromone.

Here, we sequence cDNA from the pheromone glands of females homozygous for the *HviChr20* introgression (VV) and females homozygous for the wild-type *HsubChr20* (SS) in the segregating DD23 population. Using a de novo assembled transcriptome, we find gene expression differences between transcripts from *H. virescens* and *H. subflexa* alleles of the introgressed region, and identify two lipase genes and two esterase genes from *H. virescens* as candidates contributing to acetate hydrolysis. We inactivate these *H. virescens* genes using CRISPR/Cas9 gene editing in females heterozygous for the *HviChr20* introgression (VS) and observe an increase in acetates. Homology modeling of the enzymes and docking studies with the three acetate esters produced by *H. subflexa* yields binding models consistent with hydrolytic activity. Overall, we find that these lipases and esterases significantly affect the final amounts of acetate esters in the females’ sex pheromone, which in the *H. subflexa/virescens* system, play a key role in reproductive isolation.

**Results**

**Dominant effect of *H. virescens* QTL for reduced acetate levels**

Through continuous backcrossing one of the two major QTLs for acetate levels, we isolated this QTL (2.4 C M at one end of Chromosome 20) into an otherwise complete *H. subflexa* genomic background. We refer to this introgressed line as DD23. VV (homozygous) and VS (heterozygous) DD23 females showed significantly lower acetate levels than SS (wild type) *H. subflexa* (Tukey post-hoc test, *p* < 0.001) (Fig. 2). Also, the introgression of Chr20-QTL from *H. virescens* into *H. subflexa* has a dominant effect, as VS females had similarly low levels of acetates as VV (Tukey post-hoc test, *p* = 0.585).

**Assembly of the DD23 pheromone gland reference transcriptome**

We first generated a reference transcriptome through RNAseq reads assembly of RNA extracted from VV and SS glands. After filtering this transcriptome contained 18343 contigs, with an N50 of 2603 (Supplementary Table S1). To assess the transcriptome quality, we used the tool BUSCO and found 1480 (89.26%) of the 1658 BUSCO genes (Supplementary Table S1). 1247 of these genes were found in a single complete copy and 233 were found in duplicated complete copy. We also used the Transrate tool that use alignment of the reads on the contigs to assess the quality of the assembly. The overall assembly score was 0.317, while the unfiltered transcriptome assembly score was 0.247 and the mean optimized assembly score for arthropod transcriptomes tested by Transrate is 0.256. The number of segmented contigs was 3560 in our reference transcriptome, with an uneven read coverage along their sequence, versus 14154 for the unfiltered transcriptome. These quality metrics led us to be confident about the quality of the DD23 pheromone gland transcriptome, which we used to perform a differential expression analysis.
Identification in the DD23 pheromone gland reference transcriptome of candidate lipases and esterases putatively involved in the difference in acetate levels in the pheromone

To determine which genes were differentially expressed in the sex pheromone glands of the different types of females, we analyzed the transcriptomes of these glands after building a reference transcriptome (see Supplementary Results). We considered differentially expressed contigs when we found a significant log2 fold change in expression with an absolute value of 2 or more. This first filtering revealed 89 differentially expressed contigs, none of which were annotated by Blast2Go with putative functions in pheromone biosynthesis (see Supplementary Table S2). However, among these differentially expressed contigs, five were annotated by Blast2Go as putative lipases (38088_c0_seq4, 38088_c0_seq5, 38579_c0_seq3, 39873_c1_seq2 and 39873_c1_seq3) and one as a putative esterase (comp39435_c1_seq17) (Supplementary Table S2). As the GO terms predicted that the genes represented by these contigs are putatively involved in acetate degradation, we considered these contigs as candidate transcripts for explaining the phenotypic difference in acetate levels between VV and SS.

In vivo expression of candidate lipases and esterases

As a first step in verifying in silico observations, we confirmed the sequence of candidate transcripts by Sanger sequencing. Consistent with its low expression levels in the RNAseq experiment, comp38088_c0_seq5 could not be amplified from *H. virescens* pheromone gland cDNA. Similarly, comp38579_c0_seq3 could not be amplified from *H. virescens* pheromone gland cDNA. The sequences resulting from Sanger sequencing were named: LipX (38088_c0_seq4; OK556469, OK55646970), LipZ (38088_c0_seq5; OK556475). Est1 (comp39435_c1_seq17; OK556471, OK556472), Lip38973 (39873_c1_seq2; OK556473, OK556474) and Lip38579 (38579_c0_seq3; OK556476).

We then verified the differential expression levels in the RNAseq experiment with quantitative real-time PCR experiments on pheromone gland cDNA, except for Lip38579 for which we could not find primers with satisfactory efficiency. We observed higher expression levels of LipX and Est1 in *H. virescens* and VV individuals compared to *H. subflexa* and SS females, and this difference was significant in comparing VV with *H. subflexa* and SS individuals (Games-Howell post-hoc test, *p* < 0.05, Supplementary Table S3; Fig. 3a, c). For LipZ, the expression level was significantly higher in the pheromone glands of VV and *H. virescens* females compared to SS and *H. subflexa* females (Tukey post-hoc test, *p* < 0.05, Supplementary Table S3; Fig. 3b). For Lip38973, we observed overall very low and similar expression levels in *H. subflexa*, *H. virescens* and SS female pheromone glands (Fig. 3d) and therefore did not consider this gene as a candidate for further experiments.

Based on our reference DD23 pheromone gland transcriptome, we observed a number of contigs that have the same best hit in nr (NCBI) and opposite over-expression patterns in the differential expression analysis. For the transcript we re-sequenced, we observed that our reference transcriptome included pairs of contigs matching either mostly the *H. subflexa* or the *H. virescens* alleles of the genes. The sequence divergence between homologous alleles gives rise to mapping the reads to the contigs in a species-specific way. When we blasted the contigs considered as differentially expressed in Supplementary Table S2 against the *Bombyx mori* genome, we found that most of their *Bombyx* best hits were distributed along one end of Chromosome 20 (Supplementary Table S4). Many of these Chromosome 20-mapping contigs occurred in pairs, one representing the *virescens* allele and the other representing the *subflexa* allele. Consequently, any gene with enough sequence divergence between these two species on the end of Chromosome 20 could be over-represented, whether or not there was a genuine expression difference among the alleles.

By separately mapping reads from SS pheromone glands to alleles found in SS individuals, and mapping reads from VV pheromone glands to alleles found in VV individuals (which are mostly from the *subflexa* genome except for the *virescens*-derived end of Chromosome 20), we found that *Est1*, *LipX*, and *LipZ* are the only genes with a significant over-expression in VV pheromone glands compared to SS (Supplementary Table S5). *LipZ* is the most differentially expressed gene between VV and SS, which is mostly due to the fact that it has a very low expression in the SS pheromone glands. As *LipY* is absent from the *H. virescens* genome, its expression ratio is zero in SS individuals. Thus, the two pairs of tandemly repeated genes (*LipX-Z* and *Est1-Z*) that had surfaced in the original analysis are most probably involved in the difference in the amount of acetates between the SS and VV female pheromones.

In vivo functional characterization of candidate genes

To determine the role of the identified candidate genes differentially expressed between SS and VV individuals, we performed loss-of-function studies by generating mutant DD23 lines using CRISPR/Cas9, where we knocked out the *H. virescens* alleles of *LipX*, *LipZ*, *Est1*, and *Est2* in the introgressed segment of Chr20 (Fig. 4). To avoid functional compensation between closely related enzymes, we targeted multiple genes at once in each knock-out line. In the esterase-only knock-out line, we found intermediate percentages of acetate levels compared to VS and SS (Games-Howell post-hoc test, *p* = 0.05, Supplementary Table S6; Fig. 5). A similar pattern was observed when we log-contrasted the total amount of acetate esters to tetradecanal (14:Ald) to break data interdependency (see “Methods”); Supplementary...
Double and lipase only knockouts lines had similar levels compared to SS females and significant differences in the esterase knock-out line, which is most probably due to one VS outlier (Supplementary Fig. S2a). In comparing differences in the three other components that affect male response (Z-9-hexadecanal (Z9-16:Ald), Z-11-hexadecanal (Z11-16:Ald), and Z-11-hexadecanol (Z11-16:OH)), we found that the lipase knock-out line as well as the four-genes knock-out line had similar log-contrast levels of Z9-16:Ald, Z11-16:Ald and Z11-16:OH as SS females, but significantly lower levels than VS females (Supplementary Fig. S2–o). The esterase knock-out line had similar levels of the three compounds as VS and SS females apart from a significantly higher levels of log-contrast Z11-16:OH compared to SS females (Supplementary Fig. S2–o). When comparing relative percentages, 14:Ald levels were similar between VS and esterase knockout females and significantly lower compared to SS females. Double and lipase only knockouts lines had similar levels compared to SS. All lines had similar levels of Z9-16:Ald (Supplementary Fig. S2h). VS and esterase knock-out line had significantly higher proportion of Z11-16:Ald in comparison to the other genotypes (Supplementary Fig. S2i). The SS and lipases knock-out lines had a significantly smaller relative percentage of Z11-16:OH in their pheromone compared to VS. The percentage of Z11-16:OH in the double and esterase-only knock-out lines were not significantly different from those in the VS lines (Supplementary Fig. S2j).

Docking of pheromone compounds in the candidate enzymes

To explore the feasibility of the hydrolysis of the three H. subflexa acetates by the candidate lipases and esterases, we used in silico molecular modeling and docking studies. For comparison, we first used Spodoptera littoralis SlitCXE7, SlitCXE10 and three of their experimentally verified substrates, which include two acetate pheromone compounds35,36. We observed docking models of the SlitCXE7 and CXE10 substrates without steric clashes and with the carbonyl carbon within 4.5 Å of the catalytic serine of the enzymes (Supplementary Fig. S3). Both enzymes had been shown to hydrolyze acetate esters by heterologous expression in previous studies35,36. Using the same modeling protocol, we observed that H. subflexa and H. virescens...
isofoms of LipX, Est1, and Est2 can accommodate substrates Z-7-hexadecenylacetate (Z7-16:OAc), Z-9-hexadecenyl acetate (Z9-16:OAc), and Z-11-hexadecenyl acetate (Z11-16:OAc) in their binding pockets (Fig. 6a, b, e–h; Supplementary Fig. S4a, b, e–h). For LipZ, we only found docking models of Z11-16:OAc, not of Z7 and Z9-16:OAc in HvirLipZ (Fig. 6c, d; Supplementary Fig. S4c, d). For HsulLipZ, no docking models of tested acetate pheromone compounds were found. Overall, the binding pockets of LipX and LipZ appear less permissive than the binding pockets of Est1 and Est2 (Fig. 6, Supplementary Fig. S4a–d).

Discussion

By conducting RNAseq on female sex pheromone glands from two closely related species with acetate esters (H. subflexa) or without them (H. virescens) as well as acetate QTL introgression lines (V and SS), we identified esterases and lipase genes involved in moth sex pheromone acetate levels. Introgressing this QTL into the H. subflexa genomic background provided the opportunity to examine the role of acetate hydrolysis in affecting the final amount of acetates in female pheromone glands. This question cannot be addressed by studying female H. virescens, unless synthetic acetates are applied to the gland, as was done by Teal and Tumlinson. The added acetate esters were hydrolyzed, and Teal and Tumlinson commented on finding this apparently unnecessary hydrolytic activity in the gland. “The presence of the esterase in the pheromone gland of H. virescens is an enigma, because none of the acetates […] have been identified from extracts.”

No attempts were made to identify the responsible enzymes in these early studies. However, our introgression of a portion of H. virescens Chromosome 20 containing esterase and lipase genes provides the opportunity to test hydrolytic function in a pheromone gland that naturally produces acetates, rather than artificially adding them.

The results from CRISPR/Cas9 knockouts prove that hydrolysis will decrease the final amount of acetate esters. Our experimental design does not reveal the contribution of individual enzymes, because to avoid a possible compensatory effect we targeted both of the esterases and/or both lipases at once. We reasoned that two CRISPR/Cas9 experiments could be completed more easily than four, and in fact the low success rate as shown by the need to repeat the attempt three times justifies this. Our results show that knocking out the esterases alone has less effect on the acetate levels than knocking out the lipases (see Fig. 5 and S2), making the lipases the more likely candidates, but since knocking out the esterases alone significantly increased the acetate levels (Fig. 5), we cannot dismiss the role of esterases. Functional characterization by heterologous expression of the enzymes will be needed to confirm their enzymatic activity as well as their annotation as lipases and esterases.

We find it important to note that we previously found a second major QTL underlying acetate variation, which indicates that additional and possibly interacting enzymes are involved in acetate biosynthesis and/or degradation. Unfortunately, even after 10 years of effort, we have never been able to introgress this second QTL region from H. virescens into H. subflexa and are currently exploring different approaches to investigate the presence of potential hydrolyzing genes in this QTL and possible interaction effects.

Carboxylesterases have been extensively studied for their potential role in degradation of acetate esters in male antennae. Thus, moth pheromone compounds being degraded by an esterase is not surprising. However, it has never, to our knowledge, been shown that an esterase can have an effect on the composition of a moth sex pheromone. Lipases have rarely been studied in relation to moth pheromone metabolism. The function of lipases has been mainly considered in digestion, following work in vertebrates. However, there is some previous evidence supporting that lipases can be involved in moth pheromone biosynthesis, although not regarding the hydrolysis of the terminal compounds. In moths, the hormone PBAN, which triggers pheromone production in female pheromone glands, also activates lipase activity in the pheromone gland in some Apoditrysia (Lepidoptera) species. Du et al. highlighted the expression of some lipases, including three acidic lipases, in the female pheromone glands of Bombyx mori. Using RNAi, they found that two of the acidic lipases increase the proportion of bombykol in the female pheromone. Thus, there are precedents for the involvement of esterases and lipases in Lepidoptera sex pheromone metabolism.

To our knowledge, no publication on the pheromone composition of H. virescens females has ever reported finding acetate esters. Previous interspecific crosses of H. virescens and H. subflexa have shown that F1 hybrid females produce no or greatly reduced amounts of acetates compared to H. subflexa females. Absence of the gene(s) encoding acetyltransferases from the genome of H. virescens and their presence only in the genome of H. subflexa cannot be the explanation, because acetate esters have been found in the hairpencils of male H. virescens, as well as on H. virescens legs. Therefore, H. virescens must possess one or more acetyltransferase genes, which are expressed in the male hairpencils but not the female pheromone gland. The acetyltransferase gene(s) of H. subflexa are likewise expressed in the pheromone glands of hybrids, as well as DD23 females.

Teal and Tumlinson suggested that “the esterases present in the gland of females of H. virescens converts the acetates into alcohols as rapidly as they are produced.” They hypothesized that this hydrolytic activity in H. virescens “may act as fail-safe mechanism which converts any acetate which might enter the cuticle to the alcohol.” Another possibility is that females hydrolyze acetate esters from the hairpencils of H. virescens males, which are transferred to the female during
matings and greatly reduce attraction of subsequently encountered *H. virescens* males as well as her reproductive output \(^2\). An hydrolytic activity in and around the pheromone gland would limit the impact of this male chemical mate guarding, which would resemble the degradation by *Drosophila melanogaster* females of sex and aggregation pheromone cis-vaccenyl acetate \(^1\). Thus, the expression in the pheromone gland and the acetate esters hydrolysis activity of *HvLipX*, *LipZ*, Est1, and/or Est2 may have evolved in the trajectory of *H. virescens* as a “fail-safe” and/or “anti-mate guarding” function.

An alternative scenario is that the expression patterns and enzymatic activities of these lipases and esterases trace back to an acetate-producing ancestor. Since in moths acetates are the most commonly used pheromone compounds \(^2\), and most species in the Noctuidae contain acetates in their sex pheromone blends \(^3\), the absence of acetates in the pheromone gland is likely to be a derived state. Unveiling the role of these lipase and esterase genes in *H. virescens* mate recognition, and potentially extending our insights across Lepidoptera, presents a compelling avenue of research opened by the work presented here. To determine how these enzymes are involved in the fine tuning of acetate levels in the pheromone blend, an exploration of Lepidoptera genomes and pheromone gland transcriptomes is needed, aiming to elucidate the evolutionary history of LipX, LipZ, Est1, and Est2 orthologues along with their expression patterns in other species. Complemented by functional studies on both extant and reconstructed ancestral genes \(^4\), this approach should provide valuable insights into the role of these lipase and esterase genes in regulating Lepidoptera sex pheromone blend composition and their evolution.

Our study underlines the effectiveness of introgressing a major QTL into the genomic background of a related species for transcriptome and loss-of-function analyses, to identify new genes underlying a phenotype. Through these analyses, we revealed that lipases and carboxylesterases are involved in moth sex pheromone metabolism, specifically in the degradation of acetate esters. As the role of these enzyme families in moth sex pheromone biosynthesis was previously unexpected, this paves the way for new biochemical and molecular analyses to gain insights in the specific functions of these enzymes in moth sex pheromone biosynthesis. In addition, the attempts to identify acetyltransferases must continue, because only after identification of the relevant genes will it be possible to explain how *H. subflexa* evolved this very effective reproductive isolation mechanism from *H. virescens*. Our study also highlights that pheromone degradation needs to be considered as an important mechanism in the evolution of moth sex pheromones.

**Methods**

**Insect rearing**

The genus name *Heliothis* was recently changed to *Chloridea* for *subflexa* and *virescens* only \(^6\) but we retain *Heliothis* for continuity with the extensive prior literature. Animals were kept at 25 °C and 60% relative humidity with a reversed 14 h:10 h day-night cycle (lights off at 11:00, on at 21:00). *H. subflexa* larvae were maintained on wheat germ/soy flour-based diet (BioServ Inc., Newark, DE, USA). Adult moths were provided with a cotton roll soaked in 10% sugar water. The so-called DD23 strain was generated by hybridizing *H. virescens* and *H. subflexa*, followed by continuous backcrossing to *H. subflexa*, as described in detail previously \(^2\). In short, we generated multiple backcross lines (in order to avoid brother-sister matings which have detrimental effects in Lepidoptera \(^6\)), to conduct intercrosses. This resulted in the introgression of a terminal part of HvirChr20-QTL from *H. virescens* into a complete *H. subflexa* genomic background (Supplementary Fig. S1), which led to significantly lower acetate levels in the pheromone blend (Fig. 2). In this study, we used animals homozygous (VV), heterozygous (VS), and wild-type (SS) for this QTL. As this QTL is dominant, i.e., one V-copy is enough to reduce the acetate levels \(^3\) (Fig. 2), we used VS females in the loss-of-function analyses. Distinction between the three genotypes was made through PCR amplification of marker sequences where an EcoRI restriction site is present in V-allele and absent in the S-allele.

Maintaining the introgressed Chromosome 20 in the *H. subflexa* background over several generations required special attention. A strain of homozygous VV cannot be maintained for very long, due to inbreeding effects \(^10\) caused by homozygosity for the virescens-derived segment of Chromosome 20 as well as the *subflexa*-derived segment that has become fixed. A population segregating the three types VV, VS, and SS can be maintained for a few generations, but the frequency of the V type constantly declines due to its lower fitness. To prevent its loss, adults are screened (by PCR of DNA isolated from a single leg) before mating or mated pairs are screened after mating, and fewer SS individuals are taken to the next generation. The first round of injections used eggs laid by females in VV x VV single-pair matings. Subsequent rounds used individuals from a segregating population crossed to *H. subflexa*, therefore SS progeny had to be screened out because they would be uninformative for knockouts of the *virescens*
alleles. Occasionally the overall fitness (larval survival, pupation success, adult fertility) of the segregating population was so low that it had to be outcrossed to *H. subflexa* (which reduced the frequency of the introgressed chromosome to half its original value) and then the progeny screened so that the introgressed chromosome could be increased in frequency once again. Over the course of several years, the segregating population was lost in Amsterdam and had to be replaced from Jena, and vice-versa.

**Pheromone extraction**

For all pheromone analyses in this study, we used 2- to 4-day-old virgin female moths. Females, whose glands were used in the RNAsseq and the real-time quantitative PCR, were injected with pheromone biosynthesis activating neuropeptide (PBAN) 1–2 h before gland extraction to stimulate pheromone production, as previously done. To avoid possible side-effects of PBAN injections in our subsequent functional analysis experiments, pheromone extractions were performed only on unjected calling females, 3–4 h into scotophase. Pheromone gland extractions were conducted as described in detail previously, and summarized here. Pheromone glands were cut with microdissection scissors, soaked for 20–30 min in 50 µL of hexane containing 200 ng of pentadecane as an internal standard, and stored at −20°C until analysis. For analysis, samples were dried by sublimation under a gentle stream of N₂ and injected into a splitless inlet of a HP6890 gas chromatograph for analysis. Samples were reduced to 1 µL, and pheromone extractions were conducted as described in detail previously, and nondenaturation of the samples was confirmed by analysis on a GCMS. Pheromone glands were present in comparable amounts in all extracts, except SS and the abdomen. Pheromone glands could not be accurately quantified due to non-normality of residuals. Samples with less than a total pheromone of 500 pg were not used for the expression analysis described above. RNA was reverse transcribed using the Verso cDNA Synthesis Kit (Thermo Fisher Scientific) for the expression analysis described above. RNA was reverse transcribed using the Verso cDNA Synthesis Kit (Thermo Fisher Scientific) and primers were designed to amplify an approximately 1000 nucleotide region from the *M. sexta* sex pheromone blend (http://transdecoder.github.io/). We then used RSEM to map the reads to contigs derived from genes present in SS individuals, and mapping VV reads to contigs derived from genes present in VV individuals (Supplementary Data 1). We used the same analytic workflow described above.

**Sequencing of candidate transcripts and quantitative real-time PCR**

To confirm in silico differential expression results, we first had to confirm the sequences of the candidate transcripts, which we did by extracting RNA from *H. virescens* and *H. subflexa* female pheromone glands; from different individuals than those that provided the glands for the expression analysis described above. RNA was reverse transcribed using the Verso cDNA Synthesis Kit (Thermo Fisher Scientific), the candidate gene transcripts were amplified using DreamTaq™ DNA Polymerase (Thermo Fisher Scientific) and primers were designed to amplify an approximately 1000 nucleotide region from cDNA from *H. virescens* and *H. subflexa* pheromone glands (see Supplementary Table S7 and Supplementary Figs. S5–S8). Amplicons were sequenced using Sanger sequencing by Marcogen (Amsterdam, the Netherlands). From these sequences, we designed primers for real-time PCR to get approximately 100 bp amplicons from the alleles of both species for each target gene.

To assess the in vivo expression of the candidate genes, we extracted RNA as described above from 5-6 pheromone-extracted pheromone glands of *H. subflexa*, *H. virescens*, SS and VV females. We used 20 µl reaction of 5X HOT FIREPol® EvaGreen® qPCR Mix Plus (ROX) (Solis BioDyne, Tartu, Estonia), 2 ng of cDNA and 1 µM of primer couples for the target genes and used RPS18 as a reference gene. For primers used, see Supplementary Table S7 and Supplementary Figs. S5–S8. All biological replicates were also technically replicated. qPCR reactions and measurements were made using an Applied Biosystem 7500 Real-Time PCR System (Thermo Fisher Scientific).

**Knock-out of the candidate genes using CRISPR/Cas9**

To functionally characterize the candidate genes discovered in the previous steps, CRISPR/Cas9 knock-out experiments were performed as follows. The IDT system for CRISPR/Cas9 was used (Integrated DNA Technologies). Gene-specific crRNAs are annealed with tracrRNAs and incubated with Cas9 enzyme to form ribonucleotide particles for injection into eggs. Gene-specific guide RNAs were designed for the
two esterases (VVEst1-T1 and VVEst1-T2 for est1, VVEst2-T1 and VVEst2-T2 for est2) and the two lipases (VVLipX-T1 and VVLipX-T2 for LipX, VVLipZ-T1 and VVLipZ-T2 for LipZ), all sequences are in Supplementary Table S7 and Supplementary Figs. S5–S8). First, VV eggs were injected with Est1-Est2 guide RNA to knock out the two esterases. In a second step, VV and VV-Est1-Est2-kb eggs were injected with LipX-LipZ guide RNAs to obtain respectively a line with only the two lipase knock-outs and another line with the four gene knock-outs (Est1, Est2, LipX, and LipZ). All eggs were from 30 min to 1 h old and micro-injected using a Femtojet (Eppendorf) with a solution previously loaded in homemade glass needles. The solution was prepared by first dissolving each of the four scRNAs (Supplementary Table S7 and Supplementary Figs. S5–S8) in 1 nmol of tracrRNA to get a final concentration of 50 μM, after which 200 pmol of this scRNA+tracrRNA mix was combined with 100 pmol of IDT Alt-R Cas9.

Injection needles were filled with about 2 μl of injection solution. For esterase knockouts, the following ingredients were combined: 100 pmol of IDT Alt-R Cas9 enzyme in 1.6 μl, 150 pmol total of the guide RNAs consisting of equal parts of crRNAs for VVEst1-T1, VVEst1-T2, VVEst2-T1, and VVEst2-T2 in 3.0 μl, 50 pmol of guide RNA targeting the scarlet gene affecting larval pigmentation in 1.0 μl, and 34.4 μl H2O. The scarlet guide RNA was omitted for injections at later dates and the amount of guide RNAs was increased. Thus, the molar ratio of guide RNAs to Cas9 enzyme was 2:1. Guide RNAs were made by combining crRNAs and tracrRNAs in equimolar ratios in duplex buffer, heated at 94 °C for 2 min, and allowed to cool at room temperature. Lipase injections were the same except for the guide RNAs VVLipX-T1, VVLipX-T2, VVLipZ-T1, and VVLipZ-T2.

The gauze with the injected embryos was kept in Petri-dishes at lab temperature (20 °C) in an air-tight chamber provided with a damp sponge and checked daily. After three days, newly hatched neonates were separated in individual cups with wheat germ/soy flour-based diet (BioServ Inc., Newark, DE, USA). For some egg clutches, eggs were left uninjected to verify fertility later; these were marked on the photograph and removed with sticky tape two days later when eyespots developed so that larvae emerging from them would not cannibalize the injected eggs, which develop more slowly.

A scheme displaying the crosses and details on the CRISPR experiments can be seen in Supplementary Fig. S9. In 2019, 404 eggs on 25 different clutches were injected (average 16.16, s.d. 12.1, minimum 4, maximum 54). There was a total of 359 eggs injected with esterase guide RNAs and 45 with lipase RNAs. Fifty eggs survived the injection (12% survivorship) and neonates emerged and were collected into vials. Surviving adults were outcrossed to H. subflalexia, and separated from this method we could observe the binding of H. subflalexia and H. virescens alleles of LipX, LipZ, Est1, and Est2 using PrediSi37. Docking of the acetate pheromone compounds in candidate enzymes

We assessed whether predicted 3D structures of the candidate enzymes could accommodate the acetate pheromone compounds produced by H. subflalexia females. Structure of Z7, Z9, and Z11-16:OAc were obtained from Pherobase in PDB format and converted into PDBQT using OpenBabel75. We removed potential signal peptides from the sequences of the H. subflalexia and H. virescens alleles of LipX, LipZ, Est1, and Est2 using PrediSi37. 3D structure of the sequences was predicted using ColabFold74. Residues in the catalytic triad were identified by alignment with previously-annotated lipases and esterases (Supplementary Figs. S10–11). Ligand and enzyme files obtained were prepared for the docking software using AutoDockTools, part of MGLTools v1.5.778. 50 Ligand binding models were generated for each enzyme using Vina v1.2.97 and 10 exhaustiveness. Using Chimera X80, we computed potential hydrogen bonds and steric clashes between the ligands and the enzymes and measured the distance between the oxygen of the catalytic serine and the carbon of the carbonyl group of the ligands. We display the ligand binding models that have the lowest affinity, no steric clashes and the carbonyl carbon to serine oxygen distance less than 4.5 Å. As a positive control, we confirmed that with this method we could observe the binding of S. littoralis acetate pheromone in Silex7 and Silex10 (Supplementary Fig. S3) consistently with the experimental study of Durand et al.25,26.

Data analysis

Data and statistical analysis were performed using R Studio version 1.0.136 with R version 3.3.2. Bartlett’s test (function bartlett.test, package stats) was used to test for homogeneity of variance of the difference between the Ct observed for the reference and the target genes in the qPCR data, pheromone data of DD23 line and of the five genotypes in the loss-of-function analysis. Homogeneity of the means of the same values was tested using a Welch one-way ANOVA (function oneway.test, package stats). A Tukey or a Games-Howell post-hoc test (custom R script, http://aok12.si.gumma-u.ac.jp/R/src/tukey.R) was used for the groups with homogeneous or non-homogeneous variance, respectively. Quantitative PCR results were expressed in target copy number relative to 1000 copies of RPS18, similarly as Groot et al.21.

Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

Data availability

The H. subflalexia and H. virescens lab strains used in this study are available upon request to A. T. Groot (A.T.Groot@uva.nl). The raw reads used to assembled the H. subflalexia DD23 pheromone gland
transcriptome data generated in this study have been deposited in the NCBI database under accession code PRJNA493752. The sequences resulting from genomic DNA Sanger sequencing generated in this study have been deposited in the NCBI database under accession code OK556469, OK556470, OK556471, OK556472, OK556473, OK556474, OK556475, and OK556476. The pheromone quantification and real-time PCR data generated in this study are available in figshare under the https://doi.org/10.6084/m9.figshare.22656718. The input data for in silico docking experiment analysis data generated in this study have been deposited in figshare under the https://doi.org/10.6084/m9.figshare.24306424. Source data are provided as a Source data file. Source data are provided with this paper.

Code availability
Code for in silico docking experiment analysis used in this study has been deposited in figshare under https://doi.org/10.6084/m9.figshare.24306418.
