Synthesis, characterization and testing of a new V$_2$O$_5$/Al$_2$O$_3$–MgO catalyst for butane dehydrogenation and limonene oxidation†

Zea Strassberger, Enrique V. Ramos-Fernandez, Agnes Boonstra, Remy Jorna, Stefania Tanase* and Gadi Rothenberg*

We report the synthesis and characterization of new V$_2$O$_5$/Al$_2$O$_3$–MgO catalysts and their application in oxidative dehydrogenation and epoxidation reactions. The materials were prepared by wet impregnation under excess acid conditions. Anchoring of the desired species on the support occurs via an exchange reaction between the vanadium complex and surface hydroxyl groups. The IR and UV-Vis spectra of these catalysts indicate the presence of monomeric vanadium species at 5 wt% V$_2$O$_5$ loading, along with small amounts of polymeric species at 5 and 10 wt% V$_2$O$_5$ loadings. Electron paramagnetic resonance (EPR) spectroscopy reveals the presence of ferromagnetic VO$_2^+$ dimers following calcination at 773 K. The catalysts were then tested in two reactions, namely the gas phase oxidative dehydrogenation of $n$-butane under flow conditions at 773 K and the liquid phase epoxidation of limonene with H$_2$O$_2$. The dehydrogenation reaction gave butenes and 1,3-butadiene in moderate selectivity at 8–10% conversion. The epoxidation of limonene was less successful, giving 50–70% selectivity to the 1,2-epoxide at 10–20% conversion.

1. Introduction

Heterogeneous catalysis is somewhere between art, science and technology. The science part is more obvious to the general observer. Solid catalysts are ubiquitous in the chemical industry (over 90% by volume of all chemicals are made using heterogeneous catalysis). In this respect, the left side of the periodic table is somewhat neglected. Most catalytic studies concentrate on the electron-rich transition metals. The reason is that many of these metals can easily switch between two relatively stable oxidation states, making them ideal active site candidates. However, there are exceptions on the basic side. Vanadium, for example, is stable as V$^{2+}$, V$^{3+}$, V$^{4+}$, and V$^{5+}$. The V$^{5+}$ state is found in tetrahedral (VO$_4$), pentahedral (VO$_5$) and octahedral (VO$_6$) forms and tends to form polyoxoanions. Surface V$^{5+}$ sites are usually present as isolated monomeric VO$_4$ species at low vanadium loadings. These species are often good catalysts, thanks to their accessibility and high activity.

In this paper, we report the synthesis and characterization of a new type of vanadium catalyst supported on a combined acid–base support: Al$_2$O$_3$–MgO. The advantages of this bifunctional support are detailed elsewhere. We elucidate the oxidation states at the active site using electron paramagnetic resonance (EPR) and study the nanometric properties of the catalyst using a variety of surface and bulk techniques. These catalysts were then tested in two types of reactions: gas-phase oxidative dehydrogenation of $n$-butane under flow conditions at 773 K and liquid-phase epoxidation of limonene with H$_2$O$_2$.

2. Experimental section

The V$_2$O$_5$ precursors used were high-purity oxalic acid and ammonium metavanadate (Sigma-Aldrich; ≥99% pure). As oxide support we used Al$_2$O$_3$–MgO (a gift sample from Eurosupport). All products were identified by comparing their GC retention times to those of authentic samples.

Surface area measurements were performed by the BET method using N$_2$ at 77 K on a Thermo Scientific Surfer instrument. Samples were dried in vacuum (1.10$^{-3}$ mbar) for 3 h at 200 °C prior to the measurement.
Infrared spectra (4000–300 cm⁻¹, resol. 0.5 cm⁻¹) were recorded on a Varian 660 FTIR spectrometer equipped with a Gladi ATR device, using the reflectance technique. Ligand field spectra were obtained on a Perkin-Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique and MgO as a reference. Electron paramagnetic resonance (EPR) spectra were collected on a Bruker EMXplus instrument (magnetic field calibrated with DPPH (g = 2.0036)).

GC analysis was done using an Interscience GC-8000 gas chromatograph with a 14% cyanopropylphenyl/86% dimethyl polysiloxane capillary column (Rtx-1701, 30 m; 25 mm ID; 1 μm df). Samples were diluted in 1 ml methanol. GC conditions: isotherm at 50 °C (2 min); ramp at 2 °C min⁻¹ to 70 °C; ramp at 70 °C min⁻¹ to 140 °C; ramp at 10 °C min⁻¹ to 260 °C; isotherm at 260 °C (2 min).

2.1 Procedure for TPR experiments
Hydrogen TPR studies were carried out for all catalysts. Samples of 50 mg were loaded into a quartz U-tube reactor and pre-treated under nitrogen flow (40 ml min⁻¹) at 473 K for 30 min. The samples were cooled to room temperature and the gas stream was switched to 5% H₂/N₂ (40 ml min⁻¹). The samples were then heated to 1000 K (heating rate 10 K min⁻¹). Hydrogen consumption was determined quantitatively by a thermal conductivity detector (TCD). A water trap was placed before the TCD. Consequently, the TCD measures only the consumed hydrogen quantity.

2.2 Procedure for catalyst synthesis
Example: V₂O₅·350-5 (5% V₂O₅ on ESM 350, catalyst A). Oxalic acid solution (0.75 g, 8.1 mmol, in 50 ml water) was added to a solution of ammonium metavanadate (0.32 g, 2.7 mmol, in 100 ml water). The mixture was stirred at 900 rpm for ca. 10 min until an orange clear solution formed. This solution was added to 5 g of ESM350 support (60:40 Al₂O₃-MgO) in a 250 ml round-bottomed flask and stirred 900 rpm for 10 min at ambient temperature. The final suspension was evaporated while stirring overnight on an oil bath at 100 °C, giving a white powder. This was first dried at 120 °C for 24 h and then calcined at 500 °C for 4 h (heating rate 2 °C min⁻¹).

Catalysts B and C were similarly prepared using 5.4 mmol (0.64 g) and 8.1 mmol (0.96 g) of ammonium metavanadate and equivalent amounts of oxalic acid, respectively.

2.3 Procedure for limonene epoxidation
All reactions were run in stainless steel 40 ml autoclaves. A solution of 1.2 ml (6.2 mmol) limonene, 6 ml H₂O₂ (35% aq.), 1.3 ml (12.4 mmol) benzonitrile and 0.025 g of the catalyst in 40 ml acetone : 2-butanol (2:8) was charged in the reactor and heated to 65 °C for 6 h. Blank experiments with or without the support were performed in the same conditions. After the reaction, the reactors were cooled down to room temperature using an ice bath. Reactions were analysed by GC (anisole external standard).

2.4. Procedure for n-butane oxidative dehydrogenation
The catalyst was activated in situ before reaction in a flow of 45 ml min⁻¹ N₂ and 5 ml min⁻¹ O₂ at 500 °C. The reactions were carried out at 1 atm and 500 °C in a continuous-flow fixed-bed vertical quartz reactor (4 mm i.d.), which was controlled with a fully automated system built in-house. The partial pressures of C₄H₁₀, O₂ and N₂ were set up at 92:92:829 mbar respectively. The ratio of catalyst mass to initial n-butane mass flow, so-called weight hourly space velocity, WHSV, was 7.7 h⁻¹. A 3 mm quartz wool layer above the catalyst served as a preheating zone. Isothermal conditions were kept by diluting the catalyst bed with ground glass; the reaction temperature was continuously monitored by a thermocouple at the catalyst bed. Reactor effluents were analysed online by using both an Interscience Compact GC equipped with a TCD detector and a Porabond Q column and a mass spectrometer. The measurement analytical repeatability was better than 0.5%.

TOFs were calculated as mol of n-butane converted per hour divided by the total mol of vanadium oxide. These calculations were based on the assumption that all catalysts have a monolayer coverage of vanadium oxide. No estimation of the active site was calculated.

3. Results and discussion
3.1 Catalyst synthesis

The catalysts were prepared by wet impregnation using stoichiometric amounts of ammonium metavanadate and oxalic acid (see the Experimental section for details). The maximum amount of vanadium oxide that can form in a two-dimensional layer, e.g. monolayer coverage, depends on both the support surface area and the concentration of reactive surface hydroxyl groups. Therefore, we selected three different V₂O₅ loadings. Table 1 gives the catalyst composition and surface properties. We observed that for a good impregnation, one must use an excess of oxalic acid with respect to NH₄VO₃ (eqn (1)). This is because the acid acts both as a reducing agent and a complexing agent (eqn (1)). In these conditions, the sorption of the vanadyl complex is carried out from acidic solutions. Therefore, the surface hydroxyl groups are protonated and the support surface has a positive charge (eqn (2), where x = the number of functional groups at the oxide surface).

⁠¹ In all cases, the support was 40:60 Al₂O₃-MgO, as 5 mm extrudates.

⁠² Actual vanadium content determined by ICP. The vanadium loading divided by the surface area of the catalyst.
Both Al₂O₃ and MgO tend to polarize and be surface charged once suspended in an aqueous solution. However, the surface charge depends on the pH of the solution.²⁹ If this is below the zero point charge (ZPC), the oxide surface is positively charged and will adsorb the negatively charged vanadium complex. The ZPC is higher for MgO (pH = 12.1–12.7) than for Al₂O₃ (pH = 7.0–9.0). Therefore, the magnesia sites are more positively charged than the alumina ones. Indeed, the pH of the solution is lower at higher vanadium loadings (see ESI† for details). The measured pH of the solutions at low loadings is higher than the ZPC. This means that the surface would be more negatively charged than the alumina site. Therefore, vanadium species bind to Al₂O₃ at low loadings (5% and 10%) and to MgO at high loading (15%). This is in agreement with the IR data discussed above.

The diffuse reflectance UV-visible (DRUV) spectra of the catalysts A–C show a broad band with maxima around 260 nm, 290 nm and 315 nm, due to the ligand-to-metal charge transfer (LMCT) transitions of V⁵⁺ (see Fig. 2). These bands originate from VO₄ species in tetrahedral coordination.²¹ The spectra of B and C display a slight tail extending beyond 540 nm. This indicates the presence of small amounts of polymeric species. It also agrees with the results of Muylaert et al., who reported polymeric vanadium oxides at higher V loadings. The spectra of A and B are almost identical in the UV range. We conclude that the domain size of the dispersed vanadium species remains unchanged, while the number of polymerized vanadium species increases at higher vanadium loadings.

Vanadium oxide remains as a highly dispersed amorphous monolayer phase at low loadings.²² This phase contains isolated vanadium oxide species anchored to the surface. Our support ESM350 (60:40 Al₂O₃–MgO) has a surface area of 175 m² g⁻¹, requiring 16 wt% V₂O₅ for monolayer coverage. The XRD patterns of catalysts A–C (see also Fig. S2 in the ESI†) after calcination at 500 °C are similar to that of the MgO–Al₂O₃ support. This suggests that no crystalline V₂O₅ are present, in agreement with the IR spectra. Note that the ICP analysis shows that the vanadium loading is well below the
monolayer coverage in all catalysts. BET surface areas of the calcined catalysts at 500 °C are presented in Table 1. The BET surface area for catalysts A and C is higher than that of the support. These values are highly reproducible when using the same catalyst sample or a catalyst sample coming from a different synthesis performed in identical conditions. This suggests that some pores are washed during the synthesis. B has the lowest surface area. The BET values seem to decrease with increasing vanadia loading (catalysts A and B), but strongly depend on the active species at the support surface (catalysts B and C).\(^2^3\)

Polycrystalline vanadia can dissociate partially upon heating.\(^2^4\) It loses oxygen, resulting in V\(^{4+}\) defects. Some studies suggest that a specific reaction between the dispersed V\(^{5+}\) ion and the matrix occurs upon calcination at elevated temperatures. This results in the formation of V\(^{4+}\) even in the presence of air.\(^2^5^,2^6^\) Clary et al. showed that the presence of vanadyl units in octahedral surroundings occurs at coverage below monolayer.\(^2^7^\) This is also the case for catalysts A–C. We therefore used electron paramagnetic resonance (EPR) for estimating the presence of paramagnetic surface VO\(^{2+}\) species.

The VO\(^{2+}\) ion has a d\(^1\) electronic configuration. In the presence of a magnetic field, the electron can orient parallel or antiparallel to the magnetic field vector. This leads to two energy levels with \(m_S = \pm 1/2\). Because the nuclear spin of V\(^{4+}\) is \(I = 7/2\), a so-called hyperfine interaction between \(S\) and \(I\) can arise. This leads to a further splitting of the two electronic states into 2\(I + 1\) sublevels. The spin Hamiltonian then takes the form:

\[
H = \beta S g_B B_0 + S A I - g_S N_B S_0
\]

\[(4)\]

where \(\beta\) is the Bohr magneton, \(S\) the electron spin operator and \(B_0\) the magnetic field vector. The \(g\) tensor is determined by the interaction of the \(S\) with \(B_0\) and by the orbital angular momentum which leads to the spin–orbit coupling. Depending on the symmetry of the VO\(^{2+}\) ion, the tensors \(g\) and \(A\) may be anisotropic. For an axial symmetry, there are two \(g\) components \((g_{zz} = g_{||}\) and \(g_{xx} = g_{yy} = g_{\perp}\)). The same applies for the hyperfine tensor. Therefore, the EPR spectra of isolated VO\(^{2+}\) ions have well resolved lines corresponding to \(g_{||}\) and \(g_{\perp}\). These lines are split by the interaction with the vanadium nucleus into eight partially superimposed hyperfine structure lines. However, spin–spin dipolar or exchange interactions often occur between neighboring VO\(^{2+}\) ions. In such cases, the EPR spectra consist of single Lorentzian lines that are broadened due to spin–spin exchange interactions. Therefore, the hyperfine structure is not well-resolved.

The EPR spectra of A and B (Fig. 3 and Fig. S3–S4 in the ESI\(^f\)) at room temperature display a line centered at ca. 3300 G. This indicates the presence of VO\(^{2+}\) sites connected by oxygen bridges, forming polymeric species. The broadening is due to the effective spin–spin exchange interactions between neighboring VO\(^{2+}\) centres within the structure. For the same reason, the anisotropic \(g\) and hyperfine structures (hfs) are not well resolved. The band at half-field from the forbidden \(D_{\text{M}} = \pm 2\) transitions occurs at 1650 G. This indicates intramolecular ferromagnetic interactions in the exchange-coupled d\(^{1−d1}\) systems (VO\(^{2+}–\text{VO}^{2+}\)) and thus of a triplet ground state. It also indicates the presence of dimers at the catalyst surface. Lower temperatures give better hfs resolution, albeit with a slight decrease in signal intensity. At 30 K, the spectrum centered at 3300 G consists of the overlapping of low- and high-field parallel and perpendicular components.

A qualitative interpretation of the magnetic interactions in transition metal dimers is usually based on the interaction between pairs of natural magnetic orbitals.\(^2^8^\) The unpaired electron in the oxovanadium(IV) unit resides in a metal-centered orbital with d\(_{xy}\) character, with the oxo group oriented along the z-axis. The direct overlap pathway leads to an anti-ferromagnetic interaction when the V(O)\(_2\)V or V(O)\(_2\)V core is planar and the V–V distance is short. In an anti-coplanar configuration, the orthogonality depends on the structural parameters of the dimer core. Moreover, the direct overlap between the two magnetic orbitals is expected to be rather small. Conversely, in a ferromagnetically coupled system the two magnetic orbitals are orthogonal. In our case such a condition favors the observed ferromagnetic interaction. This suggests that the VO\(^{2+}\) dimers formed at the alumina surface have either an anti-coplanar configuration, or that the vanadyl ions sit in two different geometrical surroundings.

The absorption band due to the d–d transition ion in the range 500–800 nm (Fig. 2) is absent for catalyst A and weak for B and C. This indicates that the amount of V\(^{4+}\) is small. Thus, UV-Vis and EPR techniques are complementary for our studies. For catalysts A and B, we performed the spectroscopic analysis for both hydrated samples and non-hydrated ones (the latter were treated at 200 °C for 4 h). However, we did not observe any change in the spectra.

### 3.3 Characterization of the reduced catalyst

We further used temperature programmed reduction (TPR) to investigate the reducibility of the supported vanadium oxide.\(^2^9^\)
Fig. 4 shows the hydrogen TPR profiles of catalysts A–C. The profiles of pure V₂O₅ and the support are also shown for comparison. Pure V₂O₅ shows two reduction peaks at 937 K and 968 K, plus a broad peak at 1000 K. These three peaks correspond to the $V^{5+} \rightarrow V^{4+} \rightarrow V^{3+}$ stepwise reduction, progressing through $V_2O_5 \rightarrow V_6O_{13} \rightarrow V_2O_4 \rightarrow V_2O_3$. Conversely, the support reduces at temperatures above 1000 K. The TPR profiles of catalysts A–C reveal an intense peak at 870 K, 885 K, and 880 K respectively. The sharpness indicates a uniform distribution of the surface vanadia species. Table 2 lists the formal average oxidation states (AOS).

Using EPR, we gained further information about the nature of the reduced vanadium species. Catalysts A and B were reduced in hydrogen using the same conditions employed for TPR studies. The reduced A does not show EPR in ambient conditions. Fig. 5 shows the EPR spectra of reduced A and B recorded at 70 K and 298 K, respectively. These indicate the presence of $V^{4+}$ ions. In both cases, the unpaired electron associated with $V^{4+}$ ($d^1$) interacts with the nuclear magnetic moment of $^{51}V$ ($I = 7/2$) to give a complicated hyperfine structure. For A, the absence of the EPR spectrum at 298 K indicates the presence of $V^{4+}$ in an axial ligand field. This may arise from a distorted octahedron or tetrahedron of oxygen ions surrounding a $V^{4+}$ ion. In both octahedral and tetrahedral ligand fields, $V^{4+}(d^1)$ has excited states close to the ground state, giving short spin–lattice relaxation times. Therefore, the EPR spectra are not detectable at room temperature. A tetragonal distortion of $V^{4+}$ in B may be responsible for the EPR activity at 298 K. The perpendicular components of the EPR spectrum indicate the presence of two chemically distinct $V^{4+}$ species. This may arise from a different interaction of the $V^{4+}$ with the surface oxygen atoms of Al₂O₃ support. We suggest that the $V^{4+}$ is stabilized on alumina by removing oxygen from the V–O–V linkage in a dimeric surface vanadia species. After exposure to air, reduced catalyst A is EPR active at 298 K (see Fig. S5 in the ESI) while the spectrum of reduced B remains unchanged. All these spectra are complex and can be interpreted as a superposition of at least two signals. Both EPR and TPR data strongly indicate the coexistence of different surface vanadium species.

### 3.4 Catalytic dehydrogenation of n-butane

Following the characterization studies, we tested catalysts A–C in the oxidative dehydrogenation of $n$-butane (see the results in Fig. 6). The $n$-butane conversion for catalysts A, B and C are
3.5 Catalytic epoxidation of limonene with hydrogen peroxide

We also tested catalysts B and C in the epoxidation of (R)-limonene using hydrogen peroxide as an oxidant (eqn (5)).

These liquid-phase reactions were run in stainless steel autoclaves, using methanol as the solvent at 65 °C. Product yields were monitored by GC. The main product was the (R)-1,2-epoxide 2, with some epoxidation of the exocyclic double bond, giving the (R)-8,9-epoxide 3. Additionally, we observed small amounts of the epoxide hydrolysis product, (1S,2S,4R)-limonene-1,2-diol, as well as traces of other diols, carvone, and carveol. These minor by-products were quantified together and denoted as “Others” in Table 3. To avoid any effect of hydrogen peroxide concentration changes on the reaction rate, an 8 : 1 H2O2 : limonene molar excess was used.

In agreement with the results of Aramendia et al.,10 we observed that the presence of benzonitrile is a must for the reaction to proceed. A possible pathway for this reaction is described by eqn (6) and (7). In the first step, the catalytic reaction of benzonitrile and hydrogen peroxide gives a peroxy-carboximidic acid. Subsequently, one oxygen atom of the acid is inserted in the olefin, giving the corresponding amide and the epoxide. Indeed, we identified the amide formation. A series of control experiments showed that benzonitrile is essential. Our studies show that the selectivity towards the epoxide 2 increases when V2O5 is added on the Al2O3-MgO surface. This suggests that the limonene oxidation takes place on both the support and on the vanadium site.

Reaction conditions: 1.2 ml (6.2 mmol) limonene 1, 6.0 ml H2O2 (molar ratio 8 : 1 H2O2 : limonene), 1.3 ml (12.4 mmol) benzonitrile; 0.025 g catalyst; 40 ml acetone : 2-butanol (ratio 2 : 8), 65 °C, 6 h. a Quantitative GC-analysis using an external standard (anisole) calibration. b Blank experiment (no catalyst or benzonitrile). c Blank experiment, no catalyst. d Al2O3–MgO (40%–60%).
corresponding diols. However, only traces of limonene glycol were observed. We believe that this is due to the basic character of the support and the catalysts. Limonene glycol is likely to form by acid catalysed hydration of limonene oxide. In fact, limonene epoxidation catalysed by V2O5 on acidic supports gives polymers as the main reaction products. For catalyst B, vanadia is supported on the alumina sites and it has a high dispersion. Alumina has surface Lewis acid sites with high relative strength. A decrease of the Lewis acidic sites occurs when vanadia is highly dispersed. This is because the former aluminium uncoordinated cations will bind VOx units. Therefore, the free basic sites of the magnesia prevent the formation of limonene glycol in this case.

We also tested our reaction conditions for catalyst leaching. Leaching tests were performed in duplicate experiments using catalyst B. First, we ran our reactions under standard conditions (see the Experimental part) for 1 h with catalyst B. Then, we stopped the reaction, filtered out the catalyst and re-started the reaction without the catalyst. Three samples were collected in total: the first sample after 1 h with the catalyst, the second one after 3 h reaction without the catalyst and the third sampling at the end of the 6 h reaction, always without the catalyst. The first sampling, with the catalyst in the reaction mixture, reached a 4.5% conversion. The second sampling, after filtration of the catalyst, showed an increase of conversion up to 7.3%. The same conversion was measured at the end of the 6 h reaction (see Fig. S7 in the ESI†).

Sheldon and Arends formulated the question of leaching in three scenarios: (i) the metal does not leak and the observed catalysis is truly heterogeneous; (ii) the metal does leak but is not an active catalyst; the observed catalysis is (predominantly) heterogeneous; (iii) the metal leaches to form a (highly active) homogeneous catalyst; the observed catalysis is homogeneous. We observe only 3% improvement of the conversion, which is comparable to the background result using a bare support. Therefore, our system resembles mainly the second case, where some metal ions leach but the catalyst is predominantly heterogeneous.

3 Conclusions

Supporting vanadium oxide on a bifunctional acid/base support such as alumina–magnesia gives promising catalysts that can be used for oxidative dehydrogenation. At 500 °C and 1 atm pressure, the conversion and selectivity were stable over 24 h without coke formation. These catalysts are also useful, albeit to a lesser extent, for liquid-phase ring-epoxidation. Using IR, UV-Vis and EPR spectroscopy we identified the surface structure of V2O5 supported on Al2O3–MgO. Our results indicate the presence of both monomeric and dimeric species at the alumina surface. Importantly, EPR studies reveal a ferromagnetic coupling of the individual magnetic moments of the V4+ ions within the surface dimer species. Both TPR and EPR of the reduced catalysts indicate the coexistence of different surface vanadium species.

Funding sources
