ABSTRACT

Online reputation management is about monitoring and handling the public image of entities (such as companies) on the Web. An important task in this area is identifying aspects of the entity of interest (such as products, services, competitors, key people, etc.) given a stream of microblog posts referring to the entity. In this paper we compare different IR techniques and opinion target identification methods for automatically identifying aspects and find that (i) simple statistical methods such as TFiDF are a strong baseline for the task, significantly outperforming opinion-oriented methods, and (ii) only considering terms tagged as nouns improves the results for all the methods analyzed.

Categories and Subject Descriptors
H.3.1 [Information Storage and Retrieval]: Content Analysis and Indexing

Keywords
Microblog posts, entity profiling, aspects

1. INTRODUCTION

Online reputation management (ORM) deals with monitoring and handling the public image of entities such as people, products, organizations, companies, or brands on the web. In the field of ORM, much of the effort is focused on analyzing mentions on social web streams (such as tweets) that are relevant to the entity of interest. An important task in this area is to identify not only posts that are relevant for a given entity, but also the specific aspects that people discuss.

Aspects refer to “hot” topics that people talk about in the context of an entity and are of particular interest for companies. Aspects can cover a wide range of issues and include (but are not limited to) company products, key people, other entities, services, and events. They are typically nouns, but can also be verbs, and (rarely) adjectives. They can change over time as public attention shifts from some aspects to others. For instance, for a company releasing its quarterly earnings report, its earnings can become a topic of discussion for a certain period of time and, hence, an aspect. Identifying aspects not only helps reputation analysts in determining what people say about an entity of interest, but it also facilitates a more fine-grained sentiment analysis than is typically possible, since opinions pertaining to aspects rather than to the entity can be identified. Although aspects have been investigated in the context of, e.g., discussion fora [9], automatically determining aspects in streams of microblog posts remains an unsolved problem.

We study the following scenario. Given a stream of microblog posts related to a company [1, 7], we are interested in a ranked list of aspects that are being discussed with respect to the company. We formulate our scenario as an information retrieval (IR) task, where the goal is to provide a ranking of terms, extracted from tweets that are relevant to the company.1 We compare different methods that address this task with three main goals: (i) to analyze how state-of-the-art IR approaches perform, (ii) to see how methods tailored specifically to identifying opinion targets perform, and (iii) to create a publicly available, humanly annotated dataset to facilitate follow-up research [8].

2. IDENTIFYING ENTITY ASPECTS

We evaluate four models for identifying aspects, given an entity and a stream of microblog posts related to that entity. All models work according to the same principle: comparing a pseudo-document built from entity-specific tweets with a background corpus. This comparison allows us to score a term using a function s(t, D, C).

We compare four methods for identifying entity aspects: TF-IDF, the log-likelihood ratio (LLR) [2], parsimonious language models (PLM) [3] and an opinion-oriented method (OO) [5] that extracts targets of opinions to generate a topic-specific sentiment lexicon; we use the targets selected during the second step of this method.

Table 1 describes how the scoring function is computed by each method. As usual, if(t, D) denotes the term frequency of term t in pseudo-document D; cf(t) denotes the term frequency in the collection C and df(t) denotes the total number of pseudo-documents Di ∈ C in which the term t occurs at least once.

3. EXPERIMENTS

Determining aspects of an entity in streams of microblog posts involves two tasks. In the first task, tweets relevant to a given entity need to be identified; in the second, these tweets need to be analyzed in order to identify aspects. We focus on the second task and base our annotations on the data used for the WePS-3 ORM Task [1]. Here, the task that participating systems need to solve is to decide which tweets containing a company name are actually related to the company. In total, 99 companies are used for testing, with around 450 tweets (manually annotated for relevance) on average for each company. In our experiments we only consider the tweets that are related to a company, adding up a total of 94 companies and 17,775 tweets with an average of 177 tweets per company.

1We only consider unigrams. When a unigram is an obvious constituent of a larger, relevant aspect it is considered relevant.

2Available at http://bit.ly/profilingTwitter
We discuss regarding a company. We compute the inter-annotator agreement for relevant aspects and recognize from compound words, mentions, or hashtags and should provide insight into the hot topics discussed regarding a company. We compute the inter-annotator agreement using both Cohens’ and Fleiss’ kappa and compare the annotators’ pairwise and overall. All obtained kappa values are above 0.6, indicating a substantial agreement.

Table 2 (upper part) shows the results of all methods for identifying aspects. Since TF-IDF is the simplest approach, it is considered as the baseline. We use Student’s t-test to test for statistical significance and indicate a significant difference with $\alpha = 0.01$ using * and ** for $\alpha = 0.05$.

First, we observe that TF-IDF is a strong baseline. In terms of precision, it significantly outperforms PLM and OO, while differences between TF-IDF and LLM are not significant. The results for OO are much lower than for the other methods. Since terms that are (part of) the name of the entity were also annotated as aspects, and these terms are very frequent in the tweets related to the entity, they are often in the top of the ranking returned by the methods. This explains the high MRR values in the results.

When manually inspecting the results, we observe that the results for the frequency-based methods (TF-IDF, LLM and PLM) are very similar, while OO tends to return more subjective terms as aspects (e.g., ‘bad’, ‘terrible’, ‘wonderful’, ‘awesome’), probably because of errors in the syntactic parsing of tweets. Moreover, this approach has more difficulty to filter out generic terms (e.g., ‘new’, ‘use’, ‘today’, ‘come’).

4. CONCLUSION

We addressed the task of identifying aspects that people discuss in a stream of microblog posts related to an entity, a task at the heart of online reputation management. We modeled this task as a ranking problem and compared IR techniques and opinion target identification methods for automatically identifying aspects. We used a pooling methodology to evaluate the methods. Simple statistical methods such as TF-IDF are a strong baseline for the task. Moreover, it is difficult to identify aspects by extracting opinion targets mainly because the language used in tweets is often non-standard, hampering the performance of such techniques. Future work includes considering n-grams as aspects and applying topic modeling techniques.
