ABSTRACT

Objective: To analyze the relationship between the type I interferon (IFN) signature and clinical response to rituximab in rheumatoid arthritis (RA) patients.

Methods: Twenty RA patients were treated with rituximab (cohort 1). Clinical response was defined as decrease in disease activity score evaluated in 28 joints (DAS28) and according to EULAR response criteria at week 12 and 24. In peripheral blood mononuclear cells the presence of an IFN signature was analyzed measuring the expression levels of three interferon response genes by quantitative PCR. After comparison with healthy controls, patients were qualified as IFN high or IFN low. The data were confirmed in a second independent cohort (n = 31). Serum IFNα bioactivity was analyzed using a reporter assay.

Results: In cohort 1, there was a better clinical response to rituximab in the IFN low group. Consistently, IFN low patients had a significantly stronger reduction in DAS28 and more often achieved a EULAR response at week 12 and 24 compared to IFN high patients in cohort 2. The pooled data showed a significantly stronger decrease in DAS28 in IFN low patients at week 12 and 24 compared to the IFN high group and more often a EULAR response at week 12. Accordingly, serum IFNα bioactivity at baseline was inversely associated with the clinical response, although this result did not reach statistical significance.

Conclusion: The type I IFN signature negatively predicts the clinical response to rituximab treatment in RA, supporting the notion that IFN signalling plays a role in RA immunopathology.
INTRODUCTION

Type I interferons (IFNs) are cytokines that regulate anti-viral immune responses\(^1\). Surprisingly, in a range of auto-antibody associated auto-immune conditions a proportion of patients displays a dominant type I interferon (IFN) signature in their peripheral blood mononuclear cells (PBMCs). These diseases include rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), dermatomyositis, Sjögren’s syndrome, systemic sclerosis and multiple sclerosis\(^2-7\). In several small cohorts of patients with these conditions the presence of a type I IFN signature was associated with the presence and the titer of auto-antibodies\(^2-5,7\). It has therefore been hypothesized that patients with a type I IFN signature suffer from a pathogenetic subset of RA in which type I IFN stimulating auto-antigens enhance the humoral immune response.

Rituximab has shown clinical efficacy in many of these conditions\(^8,9\). Most of the evidence has been gathered in RA\(^10,11\). However, rituximab does not induce a clinical response in all patients and does not decrease all auto-antibodies. Type I interferons have been associated with enhancement of B cell survival, since they stimulate B cell survival directly and through the production of BlyS and APRIL. Therefore, we hypothesized that patients with a type I interferon signature respond less well to rituximab treatment. We tested this hypothesis in 2 independent cohorts of RA patients commencing rituximab treatment.

PATIENTS AND METHODS

Patients and treatment protocol. Patients were included from 2 cohorts of RA patients that were reported previously\(^12,13\). Patients had active RA (Disease Activity Score evaluated in 28 joints (DAS28) \(\geq 3.2\))\(^14\) despite methotrexate treatment. The study protocol was approved by the Ethics Committee of the participating centers (cohort 1: UMCU, cohort 2: AMC); all patients gave written informed consent.

Patients were treated with 2 infusions of 1000 mg rituximab (day 1 and 15). Pre-medication with methylprednisolone was omitted in the AMC cohort [cohort 2], as previously described\(^12\). In both cohorts the DAS28-ESR was used to evaluate disease activity. The clinical response was defined by the decrease in DAS28 at week 24 compared to baseline. Paired serum and PBMC samples were collected at baseline.

Blood sampling for RNA isolation. Blood was drawn in heparin tubes. PBMCs were isolated using a Ficoll gradient and subsequently stored at liquid nitrogen until RNA isolation.

RNA isolation was performed using the RNeasy mini kit #74106 and QIAcube #9001293 (Qiagen, Venlo, the Netherlands). A DNase digestion step was included in the protocol to remove genomic DNA. RNA concentrations were determined using NanoDrop spectrophotometer (Thermo Scientific, Wilmington, MA).

Realtime PCR. RNA (0.5 \(\mu\)g) was reverse transcribed into cDNA using a Revertaid H-minus cDNA synthesis kit (MBI Fermentas, St. Leon-Rot, Germany) according to the manufacturers’ instructions. Quantitative realtime PCR (qPCR) was performed using an ABI Prism 7900HT Sequence detection system (Applied Biosystems, Foster City, CA) using SybrGreen (Applied Biosystems). Relative expression of OAS1, ISG15 and Mx1 was normalized to 185RRNA expression.
To calculate arbitrary values of mRNA levels and to correct for differences in primer efficiencies a standard curve was constructed. An IFN score was calculated by adding the relative expression values for the three IFN-inducible genes. We defined which patients showed an increased IFN response gene expression, by calculating the 95% limits of the healthy controls; normal values were defined as the mean expression of the 3 IFN-response genes, plus 1.96 times the standard deviation).

**Reporter cell assay for IFNα.** The reporter cell assay for type I IFN has been described in detail elsewhere. In this assay, reporter cells were used to measure the ability of patient sera to induce IFN-induced gene expression. The reporter cells (WISH cells, no. CCL-25; American Type Culture Collection) were cultured with 50% patient sera for 6 h and then lysed. cDNA was made from total cellular mRNA and gene expression levels were then quantified using qPCR. Forward and reverse primers for the genes MX-1 (myxovirus resistance 1), PKR (dsRNA-activated protein kinase), and IFIT-1 (IFN-induced protein with tetratricopeptide 1), which are known to be highly and specifically induced by IFNα, were used in the reaction and relative expression determined in comparison to a housekeeping gene control (HPRT1). The type I IFN activity was calculated by determining the mean and standard deviation of the relative expression of each of the three genes in a population of healthy individuals, determining the number of standard deviations above the mean of healthy donors for each of the three genes for each patient sample, and determining the sum of those three standard deviation values.

**Serum ELISAs.** Serum levels of IgM-rheumatoid factor (RF) and anti-cyclic citrullinated peptide antibodies (ACPA; anti-CCP2 ELISA, Immunoscan RA, Mark 2, Euro Diagnostica, Arnhem, the Netherlands) were determined at baseline and weeks 4, 16, 24 and 36 after treatment. Baseline serum BAFF and APRIL levels were measured by ELISA (R&D and Bender).

**Statistical analysis.** The Student’s t test and Mann–Whitney U test were used where appropriate for comparison of baseline data between the two cohorts and IFN high and IFN low patients. Linear and logistic regression analysis was used where appropriate for prediction analyses. The Wilcoxon signed rank test for paired data was used to analyze the decrease in auto-antibodies.

**RESULTS**

**Clinical characteristics.** Cohort 1 and 2 consisted of 20 and 31 patients, respectively. The demographic and clinical features of both cohorts are shown in Table 1. The two cohorts were comparable, except for concomitant use of methotrexate.

**Relationship between type I IFN signature and baseline clinical and inflammatory characteristics.** Differences in baseline characteristics between IFN high and IFN low patients are shown in Table 2. The DAS28 did not differ between IFN high and IFN low patients, but the swollen joint count was lower in the IFN high compared to the IFN low group in both cohorts, with trends toward higher acute phase reactant levels in the IFN low groups. As expected, IFNα bioactivity in serum tended to be higher in IFN high patients. There was no statistically

significant difference in the presence or serum level of IgM-RF, ACPA, BlyS, or APRIL between IFN high versus IFN low patients, although there was a trend toward lower APRIL levels in IFN high patients.

The type I IFN signature in PBMCs predicts the clinical response to rituximab treatment.

As a primary endpoint for analysis we used the clinical response at week 24 as measured by the decrease in DAS28 and EULAR response criteria. To gain more understanding about the dynamics of the clinical response we also analysed the clinical response at week 12.

First, we performed an exploratory analysis in the test cohort, cohort 1. Six of the 20 (30%) patients had an IFN high signature. The decrease in DAS28 after 12 and 24 weeks was markedly lower in the IFN high group compared to the IFN low group, although the difference did not reach statistical significance, possibly due to the relatively small number of patients (mean ± SD: -0.52 ± 0.75 compared to -1.49 ± 1.04; \(P = 0.056, R^2 = 0.19\) at week 12 and -0.67 ± 0.9 compared to -1.70 ± 1.60; \(P = 0.15, R^2 = 0.11\) at week 24, using linear regression analysis [Figure, panel A]). When analysing the EULAR response, less IFN high patients tended to achieve a EULAR response at week 12 compared to IFN low patients (2 out of 6 versus 10 out of 14; \(P = 0.13, R^2 = 0.16\) using logistic regression analysis) but differences were less clear cut at week 24 (3 out of 6 versus 8 out of 14; \(P = 0.77, R^2 = 0.01\)).

Next, we tested the relationship between IFN signature and clinical response to rituximab in a larger, independent cohort, which served as validation cohort (cohort 2). Eighteen of 31 patients (58%) had a type I IFN high signature at baseline. Consistent with the results in cohort 1, the decrease in DAS28 12 and 24 weeks after initiation of rituximab treatment was lower in IFN high patients compared to the IFN low group (-0.77 ± 0.83 compared to -1.67 ± 0.92; \(P = 0.008, R^2 = 0.22\) at week 12 and -0.98 ± 1.60 compared to -2.30 ± 1.30; \(R^2 = 0.16\) at week 24 [Figure, panel B]). When analysing the EULAR response, less IFN high patients achieved a EULAR response compared to IFN low patients (7 out of 18 versus 10 out of 13; \(P = 0.043, R^2 = 0.18\) at week 12 and 9 out of 18 versus 11 out of 13; \(P = 0.059, R^2 = 0.17\) at week 24).

Subsequently, as we observed a comparable pattern in both cohorts, we pooled the data for univariate regression analysis. Using this approach in 51 patients, the IFN signature was a significant predictor of the decrease in DAS28 after rituximab treatment (0.71 ± 0.8 for IFN high versus 1.6 ± 0.97 for IFN low; \(R^2 = 0.20\) at week 12 and 0.90 ± 1.48 for IFN high versus 1.96 ± 1.43 for IFN low \(R^2 = 0.12\); \(P = 0.012\) at week 24 [Figure, panel C]). Less IFN high patients achieved a EULAR response at week 12 compared to IFN low patients (9 out of 24 versus 20 out of 27; \(R^2 = 0.17, P = 0.01\)) but at week 24 this relationship did not reach statistical significance (EULAR response in 12 out of 24 versus 19 out of 27, respectively; \(R^2 = 0.06, P = 0.14\)).

Analysis of the relationship between the IFN signature and the relative decrease in DAS28 after rituximab yielded similar results (Figure, panel D-F). Using multivariate regression analysis in a forward model, we found that the IFN signature remained a predictor of the decrease in DAS28 to rituximab treatment, even when correcting for SJC at baseline (\(R^2 = 0.16, P = 0.003\) and \(R^2 = 0.09, P = 0.029\) at week 12 and 24, respectively). In accordance with these findings, serum IFNα bioactivity negatively predicted the decrease in DAS28, which did not reach statistical significance (\(P = 0.06, R^2 = 0.12\) at week 12; \(P = 0.11, R^2 = 0.09\) at week 24) and the achievement of a EULAR response at week 12 (\(P = 0.055, R^2 = 0.20\) at week 12 and \(P = 0.24, R^2 = 0.07\) at week 24). Since type I interferons have been associated with enhancement of B cell survival in
the tissues, we explored whether the IFN high signature might be associated with persistence of circulating autoantibodies. The levels of IgM-RF and ACPA decreased significantly in both IFN low and IFN high patients, but the reduction of both IgM-RF and ACPA appeared indeed more pronounced in the IFN low group. In IFN high patients the IgM-RF titer (n = 19) decreased from (median [IQR]) 95 (31-248) to 46 (13 – 103) kU/ liter ($P = 0.002$) and the IgG-anti-CCP titer (n = 20) decreased from 490 (15 - 1700) to 434 (87 –1393) kU/ liter ($P = 0.004$). In IFN low patients the IgM-RF titer (n = 16) decreased from (median [IQR]) 151 (48-771) to 53 (25 – 118) kU/ liter ($P = 0.013$) and the IgG-anti-CCP titer (n = 17) decreased from 618 (143 - 788) to 270 (63 – 396) kU/ liter ($P = 0.026$).

**DISCUSSION**

In this study we found that patients with a type I IFN signature in PBMCs respond less well to rituximab treatment compared to patients without an IFN signature. A possible confounder in this study could have been the lower baseline disease activity, as measured by the swollen joint count, in IFN high patients. However, we found that the IFN signature also predicted the relative decrease in DAS28 and the decrease in DAS28 when we controlled for the swollen joint count in a multivariate regression model. We found a more pronounced difference in the clinical response between IFN low and IFN high patients at week 12 compared to week 24 after rituximab treatment. This may be caused by the relatively small size of the patient cohorts. Alternatively, IFN high patients may respond more slowly to rituximab compared to IFN low patients.

Figure 1. Difference in decrease in DAS28 after treatment between IFN high and IFN low patients. The difference in absolute and relative decrease in DAS28 after treatment between IFN high and IFN low patients was compared using linear regression analysis. Both in cohort 1 (A,D [n=20]) and cohort 2 (B,E [n=31]) patients with an IFN high signature showed a smaller decrease in DAS28 at week 12 and 24 compared to patients with an IFN low signature. Analysis of pooled data yielded similar results (C,F). Mean values and standard deviation are shown. ns = not significant, † $P<0.10$, * $P<0.05$. 

![Figure 1](image-url)
The data presented here suggest that the type I IFN signature is not just an epiphenomenon in RA, but might be involved in its pathogenesis. RA is traditionally viewed as a TNFα driven disease. This concept is amongst others based on the effectiveness of TNFα blocking agents in RA and results from genetic studies in which an association was found between TNFα related genes and ACPA positive RA versus type I IFN related genes and ACPA negative RA. According to this model ACPA positive RA is predominantly driven by TNFα, based on in vitro observations that TNFα down modulates the effects of type I IFNs and vice versa. However, the results from the current study, together with other observations, contradict this model.

First, in a recent genome wide association study both single nucleotide polymorphisms in TNF related genes and IFN related genes were associated with autoantibody positive RA. Furthermore, TNFα, IFNα and IFNβ are simultaneously expressed in RA synovial tissue. In line with these data we found that plasma TNFα levels were at least equal in IFN high compared to IFN low patients (data not shown). Taken together, these data suggest that the presence of TNFα and type I IFNs is not mutually exclusive. Instead of the single-cytokine based paradigm the data support a concept of multiple immune mechanisms that act simultaneously in RA.

In contrast to our hypothesis, we could not find a direct relationship between the response to rituximab, the IFN signature, increased levels of APRIL and BlyS and persistence of autoantibodies. This is supported by available data in the literature, which suggest a complex contribution of type I IFNs to RA pathogenesis and response to therapy. The production of type I IFN is stimulated by viruses, but also by apoptotic/necrotic material, RNA binding proteins, osteopontin and auto-antigen containing immune complexes. Furthermore, gene polymorphisms may contribute to excessive IFN signalling to sub-physiological activating stimuli. Subsequently, type I IFNs may not only stimulate the production of APRIL and BlyS and directly enhance B cell survival but also stimulate T cells and dendritic cells. At the same time, IFNβ is able to reduce the secretion of pro-inflammatory cytokines like IL-6, matrix metalloproteinases (MMPs), and prostaglandin E2 by fibroblast-like synoviocytes. In addition, IFNβ has anti-angiogenic properties and may inhibit osteoclastogenesis.

The relationship between the type I IFN signature and the humoral autoimmune response in RA was analyzed in a number of previous studies. In a first study the type I IFN signature was found in a subset of RA patients and correlated with autoantibody levels, similar to findings in other autoantibody associated diseases. Also, the type I IFN signature was identified in a subset of auto-antibody positive arthralgia patients who later developed RA. A direct relationship between the IFN signature and auto-antibody responses in RA could not be confirmed in a subsequent investigation in a larger cohort, where the IFN signature was found to occur equally often in seropositive and seronegative RA patients. However, the presence of an IFN signature was associated with persistence of ACPA after TNF blockade. Taken together with the association between polymorphisms in IFN related genes and both seropositive and seronegative RA, the current and previous data suggest that IFN related autoimmunity does not directly determine humoral autoimmunity in RA, but may promote and sustain humoral autoimmune responses in seropositive patients.

In RA the level of type I IFN bioactivity has been associated with the clinical response to TNFα blockade, although these results need to be replicated since they have been variable for different cohorts. Pilot data from an RA patient cohort treated with TNF antagonists suggested that relatively high plasma levels of type I IFN activity prior to initiation of therapy
were associated with better clinical response compared to those agents than lower plasma type I IFN activity. Patients with high type I IFN activity may respond better to TNF blockade because of the anti-inflammatory effects of their disease-associated high IFNβ levels. Alternatively, patients with an IFN signature may have an overall higher inflammatory activity compared to IFN low patients and may respond better to TNF blockade because of higher TNFα activity. This is in line with the earlier finding that patients with higher levels of synovial inflammation and synovial TNFα expression respond better to TNF blockade. The concept of a lower inflammatory activity in IFN low patients is supported by the fact that IFN low patients do not show an alternative gene activation signature in their PBMCs, but have a gene signature comparable to healthy controls.

How can we explain the finding that patients with an IFN high signature respond less well to rituximab? First, IFN high patients could have a disease that is less B cell dependent. This appears unlikely, since all patients in our study were RF and/or ACPA positive. Furthermore, current evidence suggests non-response to rituximab is associated with persistence of B cells. Conceivably, higher inflammatory activity in IFN high patients may relatively protect B cells against the depleting effects of rituximab. Although we found similar systemic levels of BLyS and APRIL in IFN high and IFN low patients, type I IFNs may promote survival of pathogenic B cells in lymphoid tissue or bone marrow. This might involve contact-dependent interactions with T cells, dendritic cells and stromal cells and membrane-bound survival factors like CXCL12, VCAM, membrane-bound BLyS or heparan-sulphate bound APRIL. With regard to the clinical response to rituximab, although BAFF and APRIL are thought to rescue B cells from B cell depletion, systemic levels of BAFF and APRIL do not predict clinical response to rituximab. Nonetheless, the reason for the decreased clinical response to rituximab in IFN high patients remains speculative until more data become available.

The decreased clinical response to rituximab in IFN high RA patients seemingly contradicts the clinical responsiveness of IFN-associated diseases to rituximab. However, the presence of high type I IFN activity does not necessarily imply that these patients will respond better to rituximab treatment. In contrast, recent randomized controlled trials failed to show clinical efficacy of rituximab in patients with lupus nephritis and patients with non-nephritis lupus, although the explanation for the negative findings is still controversial. Our data suggest that rituximab might be less effective in SLE because of the higher systemic type I IFN levels in SLE patients.

RA is a heterogeneous condition with a heterogeneous response to therapy. It would be of importance to identify biomarkers that may be used to predict the response to targeted treatment. The presence of solely the IFN signature would obviously not allow treatment decisions with regard to initiation of rituximab therapy. In general, the combination of multiple (clinical and biological) markers bears most promise to meet the needs of useful predictors of response to treatment. Our data support the evaluation of the IFN signature in future studies assessing the validity of combinations of markers in relationship to the response to rituximab treatment.

In conclusion, the results show for the first time a relationship between the IFN high signature and the clinical response to rituximab through an as yet undefined mechanism.
