Search for new physics in the dijet mass distribution using 1 fb$^{-1}$ of $pp$ collision data at $\sqrt{s} = 7$ TeV collected by the ATLAS detector

ATLAS Collaboration

1. Introduction

The Standard Model (SM) description of high energy proton–proton ($pp$) collisions is based on the framework of quantum chromodynamics (QCD) in the perturbative regime, where the most energetic collisions result from the $2 \rightarrow 2$ scattering of a pair of partons (quarks or gluons). Partons emerging from the collision shower and hadronise, in the simplest case producing two jets of particles, a “dijet”, that may be reconstructed to determine the dijet invariant mass, $m_{jj}$, the mass of the two-parton system.

Previous studies of dijet mass distributions [1–6] have shown that these analyses are sensitive to the highest mass scales accessible with hadronic final states. In the present study, the dijet mass distribution is examined in a search for resonances due to new phenomena localised near a given mass, employing a data-driven background estimate that does not rely on detailed QCD calculations.

In addition to new physics benchmarks used in previous ATLAS dijet analyses, namely excited quarks ($q^*$) [7,8], and axigluons [9–11], the present study includes a third hypothetical object: the colour octet scalar ($s_8$), one of many possible exotic colour resonances. Any of these objects could produce a peak in the dijet spectrum in the vicinity of their mass.

The present study is based on $pp$ collisions at a centre-of-mass (CM) energy of 7 TeV produced at the CERN Large Hadron Collider (LHC), measured by the ATLAS detector. This data set corresponds to an integrated luminosity of 1.0 fb$^{-1}$ recorded by ATLAS. Dijet masses up to −4 TeV are observed in the data, and no evidence of resonance production over background is found. Limits are set at 95% C.L. for several new physics hypotheses: excited quarks are excluded for masses below 299 TeV, axigluons are excluded for masses below 3.32 TeV, and colour octet scalar resonances are excluded for masses below 1.92 TeV.
jet is given by \( y \equiv \frac{1}{2} \ln \left( \frac{y_1 + y_2}{y_1 - y_2} \right) \). The rapidities of the two highest \( p_T \) jets are denoted by \( y_1 \) and \( y_2 \), and the corresponding rapidity of these partons in their mutual CM frame is \( y^* \equiv \frac{1}{2} (y_1 - y_2) \).

2. Jet reconstruction and event selection

Individual jets are reconstructed using the anti-\( k_t \) jet clustering algorithm [15,16] with the distance parameter \( R = 0.6 \). The inputs to this algorithm are clusters [17] of calorimeter cells with energy depositions significantly above the measured noise. Jet four-momenta are constructed as the vectorial sum of clusters of cells, treating each cluster as an \((E, \vec{p})\) four-vector with zero mass, assuming that the corresponding particle stems from the primary vertex.

The jet four-momenta are then corrected [18] as a function of \( \eta \) and \( p_T \) for various effects, the largest of which are the hadronic shower response and detector material distribution. This is done using a calibration scheme based on Monte Carlo (MC) studies including full detector simulation, and validated with extensive test beam [19] and collision data [20–22] studies. Measured dijet mass distributions are not corrected for detector resolution, which, in terms of mass smearing, is \( \sigma_{\text{m}} / m_{jj} \approx 5\% \) at \( m_{jj} \approx 1 \text{ TeV} \), drops to 4.5\% at 2 TeV, and asymptotically approaches 4\% at \( m_{jj} \) of 5 TeV and above.

The event selection starts with the first-level trigger, which selects events that have at least one large transverse energy deposition in the calorimeters, with the transverse energy threshold selecting events that have at least one large transverse energy deposition in the calorimeters, with the transverse energy threshold above.

The current data set has been recorded using a jet trigger that requires to the smooth functional form describing the QCD background. The bin-by-bin significance of the data-background difference is shown in the lower panel. Vertical lines show the most significant excess found by the BUMPHunter algorithm (see text).

Fig. 1. The reconstructed dijet mass distribution (filled points) fitted with a smooth functional form describing the QCD background. The bin-by-bin significance of the data-background difference is shown in the lower panel. Vertical lines show the most significant excess found by the BUMPHunter algorithm (see text).

4. Search for resonances

As a more sensitive test, the BUMPHunter algorithm [24,25] is used to establish the presence or absence of a resonance in the dijet mass spectrum. To optimise the sensitivity of this algorithm, the \( m_{jj} \) binning strategy is to establish a minimum width for resonances to be considered physical. To this end, the relatively narrow \( q^* \) \( m_{jj} \) template from full MC simulation [26], described below for subsequent studies, has been used to establish the binning. If the width of the resonance is defined as \( \pm 1 \sigma \), the greatest sensitivity at the minimum width is achieved by setting the bin width to \( 1 \sigma \), half the resonance width. The final result of this procedure is that the variable bin sizes are typically 6.5\% to 7.0\% of \( m_{jj} \) in width, somewhat wider than detector resolution due to the finite natu-
eral width of $q^*$, which varies between about 3% and 3.5% of the $q^*$ mass.

In the current implementation, the BUMPHunter algorithm searches for the signal window with the most significant excess of events above background. Starting with a two-bin window, the algorithm increases the signal window and shifts its location until all possible bin ranges, up to half the mass range spanned by the data, have been tested. The most significant departure from the smooth spectrum (“bump”) is defined by the set of bins that have the smallest probability of arising from a background fluctuation assuming Poisson statistics.

The BUMPHunter algorithm accounts for the so-called “look elsewhere effect” (or “trials factor effect”) [27] by performing a series of pseudoexperiments to determine the probability that random fluctuations in the background-only hypothesis would create an excess as significant as the one observed anywhere in the spectrum. Variable width binning reduces the penalty due to this effect, while retaining sensitivity.

To prevent any new physics signal from biasing the background estimate, if the biggest local excess from the background fit has a $p$-value smaller than 0.01, this region is excluded and a new background fit is performed. No such exclusion is needed for this data set.

The most significant discrepancy identified by the BUMPHunter algorithm in the observed dijet mass distribution reported in Fig. 1 is a 2-bin excess in the interval 1.16 to 1.35 TeV. The probability of observing such an excess or larger somewhere in the mass spectrum for a background only hypothesis is 0.82. This test shows that there is no evidence for a resonance signal in the $m_{jj}$ spectrum.

### 5. New physics models

Exclusion limits are set on three new physics scenarios expected to give rise to resonant dijet production.

For the first of these, excited quarks, $q^*$, a $q g \rightarrow q^*$ production model [7,8] is used, with the assumption of spin 1/2 and quark-like SM coupling constants. The compositeness scale ($\Lambda$) is set to the $q^*$ mass. Signal events are produced using the Pythia event generator [28], a leading-order parton-shower MC generator, with the MRST2007LO* [29] parton distribution functions (PDF’s), with settings established by the ATLAS default MC10 [30] Monte Carlo tune. The renormalization and factorization scales are set to the mean $p_T$ of the two leading partons for each event. Pythia is also used to decay the excited quarks to all possible SM final states, which are predominantly $qg$, but also $qW$, $qZ$, and $q\gamma$. The generated events are passed through the detailed simulation of the ATLAS detector [26], which uses the GEANT4 package [31] for simulation of particle transport, interactions, and decays. The simulated events are then reconstructed in the same way as the data to produce predicted dijet mass distributions that can be compared with the observed distributions.

The second model is axigluon production [9–11] via an interaction given by the Lagrangian

$$\mathcal{L}_{A_{qg}} = g_{\text{QCD}}^q A_{qg} \mu \nu \tau \gamma \phi,$$

where $g_{\text{QCD}}^q = 4\pi \alpha_s$ is the QCD coupling constant and $A_{qg}$ is the axigluon field representing a massive state with axial coupling to quarks. Parity conservation prevents the axigluon from coupling to two gluons. Parton-level events are generated, at leading-order approximation, using the CalcHEP Monte Carlo package [32], for chosen masses, $m$, of the axigluon. The MRST2007LO* PDF set was used. The axigluon dijet mass has longer tails at high and low masses than the $q^*$ distribution, but these two shapes are interchangeable within the range 0.7m to 1.3m for all masses of interest.

Since the axigluon tails outside this range are well below the SM background, the predicted signal may be analyzed by cutting events beyond this range and accounting for the reduced acceptance. The axigluon MC prediction for $\sigma \times A$, the production cross section within the acceptance, is defined to include these cuts by applying them at the level of CalcHEP generation, along with the kinematic cuts in $p_T$ and rapidity. In the limit setting analysis, these axigluon results are compared to the observed $\sigma \times A$ limits from the $q^*$ analysis. This method is discussed in more detail in Section 6.

The third resonant hypothesis, the colour octet scalar ($s^8$) model, is a prototype for many possible exotic coloured resonances [12]. Colour octet resonances can couple to gluons, which have large parton luminosity at the LHC. One possible interaction is

$$\mathcal{L}_{s^8} = g_{q^8}^{ABC} A_{s^8} F_{\mu \nu} F^{\mu \nu},$$

where $A_{s^8}$ is the colour octet scalar field, $A_s$ is the scalar coupling (assumed to be unity), and $g_{q^8}^{ABC}$ is the SU(3) isoscalar factor; $A_s$ is the new physics scale which is set to the resonance mass, $M_{s^8}$. This model leads to a very simple event topology, with two gluons in the initial and final states, yielding high $p_T$ dijets. MadGRAPH 5 [33] is used to generate parton level events at leading-order approximation. Pythia with CTEQ6L1 PDFs is used in this generation, with the ATLAS MC09* tune [34]. These samples are processed through the full ATLAS detector simulation.

The observed limits on $s^8$ are less strict than the corresponding $q^*$ limits, in part because the $s^8$ signal is much wider than $q^*$. Much of this width increase is due to final state radiation, which is larger for gluon-jets than for quark-jets. In addition, the initial state for $s^8$ production contains gluons, which have small parton density at high mass. Thus, $s^8$ are much more likely to be off-mass-shell than $q^*$.

### 6. Model dependent limit setting

In the absence of any observed significant discrepancy from the zero-signal hypothesis, the Bayesian method documented in [6] is used to set 95% credibility-level (CL) upper limits.

Bayesian credibility intervals are set by defining a posterior probability density from the Poisson likelihood function for the observed mass spectrum, obtained by a fit to the background functional form and a signal shape derived from MC simulations. A prior probability density constant in all positive values of signal parameterization uncertainty is taken from the fit results. Since the axigluon tails outside this range are well below the SM background, the predicted signal may be analyzed by cutting events beyond this range and accounting for the reduced acceptance. The axigluon MC prediction for $\sigma \times A$, the production cross section within the acceptance, is defined to include these cuts by applying them at the level of CalcHEP generation, along with the kinematic cuts in $p_T$ and rapidity. In the limit setting analysis, these axigluon results are compared to the observed $\sigma \times A$ limits from the $q^*$ analysis. This method is discussed in more detail in Section 6.

The observed limits on $s^8$ are less strict than the corresponding $q^*$ limits, in part because the $s^8$ signal is much wider than $q^*$. Much of this width increase is due to final state radiation, which is larger for gluon-jets than for quark-jets. In addition, the initial state for $s^8$ production contains gluons, which have small parton density at high mass. Thus, $s^8$ are much more likely to be off-mass-shell than $q^*$.
to Gaussian probability distributions and convolving them with the Bayesian posterior probability distribution. Credibility intervals are then calculated numerically from the resulting convolutions. No uncertainties are associated with the theoretical model of new physics, as in each case the model is a benchmark that incorporates a specific choice of model parameters, of PDF set, and of MC tune. Previous ATLAS studies have already explored the impact of different MC tunes and PDF sets on the q-parametric curves.

In 2011, the instantaneous luminosity has risen to a level where corrections must be made for multiple pp collisions occurring in the same bunch crossing ("pileup"), whose presence affects the measurement of calorimeter energy depositions associated with the hard-scattering event under study. All simulated samples used in this analysis include a Poisson distributed number of MC minimum bias events added to the hard interaction to account for "in-time" pileup caused by additional collisions in the same bunch crossing. Further account must be taken of "out-of-time" pileup originating from collisions in bunches preceding or following the one of interest, due to the long response time of the liquid argon calorimeters. With the 50 ns bunch spacing in the LHC for these data, up to 12 preceding bunches and 1-2 following bunches contribute to out-of-time pileup. Although the conditions modelled in MC are realistic, they may not perfectly match the data due to bunch train structure and instantaneous luminosity variations in the LHC. The MC events are therefore reweighted to remove these residual differences. Following this procedure the pileup description in MC is sufficiently good that no additional uncertainty on the JES is required for jets with $p_T > 100$ GeV.

The resulting limits are shown in Fig. 2. For excited quarks, the acceptance $\mathcal{A}$ ranges from 37 to 51% for $m_{q^*}$ varying from 0.8 to 5.0 TeV, and is never lower than 47% above masses of 1.1 TeV. The main impact on the acceptance comes from the rapidity requirements. Using the theoretical prediction for $q^*$ production described above, the expected mass limit at 95% CL is $2.81$ TeV, and the observed limit is $2.99$ TeV.

The axigluon results are obtained from the $\sigma \times \mathcal{A}$ limits determined from the $q^*$ analysis. The axigluon theoretical prediction is derived from the cross section provided by CalcHEP at each simulated mass, $m$, within the restricted mass range 0.7 to 1.3 TeV, after applying the kinematic selection. Using the axigluon theoretical $\sigma \times \mathcal{A}$ thus defined, the expected axigluon mass limit at 95% CL is $3.07$ TeV, and the observed limit is $3.32$ TeV. This method has been confirmed by full simulation of axigluon samples at three mass points, showing that the differences between parton level and full simulation are negligible compared to the effects of other uncertainties.

Fig. 2(b) shows the limits on the accepted cross section $\sigma \times \mathcal{A}$ for colour octet resonances. The expected mass limit at 95% CL is $1.77$ TeV, and the observed limit is $1.92$ TeV. Since the colour octet scalar cross section decreases much more rapidly with $m$ than those for excited quark and axigluon production, the resulting limits are considerably lower.

For all three models used in these studies, if systematic uncertainties had not been included the exclusion limits would be approximately 60 GeV higher.

7. Model independent limit setting

In addition to specific theoretical models, limits are set to a collection of hypothetical signals that are assumed to be Gaussian-distributed in $m_{jj}$ with mean ($m_C$) ranging from 0.9 to 4.0 TeV and standard deviation ($\sigma_C$) from 5% to 15% of the mean. Systematic uncertainties are treated using the same methods as applied in model dependent limit setting. The only difference for the Gaussian analysis arises from the decay of the dijet final state not being simulated. In place of this, it is assumed that the dijet signal distribution is Gaussian in shape, and the JES is adjusted by modelling it as an uncertainty of 4% in the central value of the Gaussian signal.

The resulting limits on $\sigma \times \mathcal{A}$ for the Gaussian template model are shown in Fig. 3. Relative to previous studies [6] they are substantially improved in the region above 900 GeV. These results may be utilised to set limits on new physics models beyond those considered in these studies, using the procedure described in Appendix A.

---

Fig. 2. The 95% CL upper limits on $\sigma \times \mathcal{A}$ as a function of particle mass (black filled circles). The black dotted curve shows the 95% CL upper limit expected from Monte Carlo and the light and dark yellow shaded bands represent the 68% and 95% contours of the expected limit, respectively. Theoretical predictions for $\sigma \times \mathcal{A}$ are shown in (a) for excited quarks (blue dashed) and axigluons (green dot-dashed), and in (b) for colour octet scalar resonances (blue dashed). For a given new physics model, the observed (expected) limit occurs at the crossing of its $\sigma \times \mathcal{A}$ curve with the observed (expected) 95% CL upper limit curve. (For interpretation of the references to colours in this figure legend, the reader is referred to the web version of this Letter.)
8. Conclusion

The dijet mass spectrum measured by the ATLAS experiment has been examined in a search for resonances from new phenomena, using 1.0 fb$^{-1}$ of 7 TeV pp collision data taken in 2011. The observed distribution, which extends up to masses of $\lesssim$ 4 TeV, is in agreement with a smooth function representing the SM expectation. No evidence for the production of new resonances is found. 95% CL mass limits using Bayesian methodology have been calculated for excited quarks and axigluons, the current results exceed the limits obtained by ATLAS with the 2010 data by approximately one TeV. Exclusion limits on colour octet scalar resonances have been established for the first time in ATLAS. The limits reported in this Letter are the most stringent to date.

Appendix A. Setting limits on new models

The following procedure is appropriate for resonances that are approximately Gaussian near the core, and with tails that are well below the background. For convenience, the results of Fig. 3 are provided in Table 2.

(1) For a MC sample generated with the mass of the hypothetical new particle set to $m_{G}$, compute an initial acceptance including both statistical and systematic uncertainties.

(2) Approximate the branching ratio into dijets. Then apply the kinematic cuts on the parton $p_{T}$ and $|\eta|$ used in this analysis. (2) Approximate the reduction of acceptance due to the calorimeter (temporary) readout problem by eliminating events where a parton enters the

Fig. 3. The 95% CL upper limits on $\sigma \times A$ for a simple Gaussian resonance decaying to dijets as a function of the mean mass, $m_{G}$, for four values of $\sigma_{G}/m_{G}$, taking into account both statistical and systematic uncertainties.
region −0.1 to 1.5 in \( \eta \), and −0.9 to −0.5 in \( \phi \). (Indicatively, the acceptance of \( q^* \) is reduced by a factor 0.92.) (3) Smeared the signal mass distribution to reflect the detector resolution. In the absence of a better detector simulation tool, use the mass resolution given in Section 2, which is derived from full ATLAS simulation. (4) Since a Gaussian signal shape has been assumed in determining the limits, any long tails in the reconstructed \( m_{jj} \) should be removed in the sample under study. The recommendation (based on optimization using \( q^* \) templates) is to retain events with \( m_{jj} \) between 0.8M and 1.2M. The mean mass, \( m \), of this truncated signal should be calculated. (5) The fraction of MC events surviving the first four steps determines the modified acceptance, \( \mathcal{A} \). (6) From Table 2 select \( m_C \) so that \( m_C = m \). If the exact value of \( m \) is not among the listed values of \( m_C \), check the limit for the two values of \( m_C \) that are directly above and below \( m \), and use the larger of the two limits to be conservative. (7) To retain enough of the information in the full signal template, and at the same time reject tails that would invalidate the Gaussian approximation, the following truncation procedure is recommended. For this mass point, choose a good choice is empirically found to be \( \sigma_C = (1.2M − 0.8M)/5 \). This \( \sigma_C \) corresponds to a Gaussian distribution contained within the truncation interval of [0.8M, 1.2M], since the interval [0.8M, 1.2M] corresponds to \([m_C − 2.5\sigma_C, m_C + 2.5\sigma_C]\).

For the \( q^* \) case a good choice is \( \sigma_C = (1.2M − 0.8M)/5 \) so that 95% of the Gaussian spans \( 4 \times (0.4/5)M \). Use this value to pick the closest \( \sigma_C/m_C \) value, rounded up to be conservative. (8) Compare the tabulated 95% CL upper limit corresponding to the chosen \( m_C \) and \( \sigma_C/m_C \) values to the \( \sigma \times \mathcal{A} \) obtained from the theoretical cross section of the model multiplied by the acceptance defined in step (5) above.
