Received 24 December 2012 / Accepted 11 February 2013

ABSTRACT

Cassiopeia A was observed using the low-band antennas of the LOw Frequency ARRay (LOFAR) with high spectral resolution. This allowed a search for radio recombination lines (RRLs) along the line-of-sight to this source. Five carbon RRLs were detected in absorption between 40 and 50 MHz with a signal-to-noise ratio of >5 from two independent LOFAR data sets. The derived line velocities (\(v_{LSR} \sim -30 \text{ km s}^{-1}\)) and integrated optical depths (\(\sim 13 \text{ s}^{-1}\)) of the RRLs in our spectra, extracted over the whole supernova remnant, are consistent within each LOFAR data set and with those previously reported. For the first time, we are able to extract spectra against the brightest hotspot of the remnant at frequencies below 330 MHz. These spectra show significantly higher (15–80 percent) integrated optical depths, indicating that there is small-scale angular structure of the order of ~1 pc in the absorbing gas distribution over the face of the remnant. We also place an upper limit of 3 x 10^{-4} on the peak optical depths of hydrogen and helium RRLs. These results demonstrate that LOFAR has the desired spectral stability and sensitivity to study faint recombination lines in the decameter band.

Key words. ISM: clouds – radio lines: ISM – ISM: individual objects: Cassiopeia A

1. Introduction

Radio recombination lines (RRLs) arise from ions recombining with electrons in diffuse, partially ionised gas. At high principal quantum numbers (i.e., \(n > 200\) at frequencies \(\lesssim 1\) GHz), RRLs are an important probe of the temperature and density of the cool (\(T \lesssim 100\) K) interstellar medium (e.g., Payne et al. 1989; Konovalenko 1984). RRL measurements have distinct advantages over other tracers of the ionised gas; the extinction caused by dust and the contamination from other sources are negligible. However, there have been only a limited number of surveys that have studied RRLs from carbon at low radio frequencies (\(\lesssim 330\) MHz; e.g. Erickson et al. 1995; Kantharia & Anantharamaiah 2001; Roshi et al. 2002). Also, the low angular resolution of these early surveys, from several degrees to around 6 arcmin, did not allow the location of the line-emitting gas to be determined, and also limited their capability to detect faint RRL sources due to beam dilution effects.

The LOow Frequency ARRay (LOFAR; Stappers et al. 2011; van Haarlem et al. 2013) is a new-generation radio telescope, which given its unique design, can be used to make sensitive surveys for RRLs with high spectral and spatial resolution. LOFAR comprises thousands of antennas arranged in (currently) 41 stations spread across the Netherlands and other European countries. By design, LOFAR provides excellent baseline coverage, particularly in the inner 3 km core-region, where over half of the collecting area is contained. The low-band antennas (LBAs) of LOFAR, although optimised for frequencies above 30 MHz, cover the frequency range from 10 to 90 MHz. The high-band antennas (HBA) cover the frequency range from 110 to 250 MHz. This large observable frequency window makes LOFAR an ideal instrument for carrying out studies of the ISM with low-frequency RRLs.

In this Letter, we present the first spectral line measurements made using the LBA system of LOFAR. We target carbon RRLs in absorption towards the supernova remnant Cassiopeia A (Cas A), which is one of the brightest continuum sources in the sky and has a sightline that is already known to display strong carbon RRLs in low frequency spectra (see Stepkin et al. 2007, and references therein). In Sect. 2, we present our LOFAR commissioning observations and data analysis steps. Our carbon RRL detections are presented in Sect. 3, and we discuss these detections and present our conclusions in Sect. 4.
2. Observations and data reduction

The data sets for our RRL study are taken from two LOFAR commissioning observations of Cas A in the 30 to 90 MHz (LBA) band. The first data set (Data-1) was taken on 2011 May 4 using the 16 core stations and 7 remote stations that were constructed at the time, giving baselines up to about 24 km. These data were taken with 1-s visibility integrations and 244 separate frequency subbands, each with a bandwidth of 195 kHz and 256 spectral channels. The second data set (Data-2) was observed on 2011 October 15 using 24 core stations and 8 remote stations, and had a maximum baseline length of about 83 km. Data-2 was taken in a multi-beam mode that is used for standard continuum observations, with one beam on Cas A and a second beam on Cygnus A. This resulted in only half of the available bandwidth being used for the observation of Cas A. Also, a coarser spectral resolution of 64 spectral channels within each of the 122 subbands of 195 kHz bandwidth was used. The visibility integration time was again 1 s. After the first step of interference removal using the AOFlagger routine (Offringa et al. 2010), the data were averaged in time and/or frequency as required.

In total, we produced 3 data sets for our work. First, to make a continuum image of Cas A, we produced an intermediate data set from Data-1 that had a coarse spectral resolution of ~50 kHz channel\(^{-1}\) in order to speed up the calibration process later. Next, we created two RRL data sets. For Data-1, we included only those baselines between the separate core-stations (~2.6 km) and retained the full spectral resolution of 762 Hz channel\(^{-1}\). Data-2 was processed to retain a spectral resolution of 3.1 kHz channel\(^{-1}\) and to also include longer baselines (~24 km) so that spectra could be extracted from individual regions across the supernova remnant. For these two RRL data sets, we decided to concentrate our search to those frequencies between 40 to 50 MHz. This was because the RRL absorption was expected to be stronger at the lower end of the LBA spectrum due to the steep broadband spectral energy distribution of Cas A. The lower frequency end of the search window was chosen because the level of terrestrial interference increases below 40 MHz (Offringa et al. 2013). The resulting time and frequency resolution for each data set after these preprocessing steps are summarised in Table 1.

We initially calibrated our continuum data using the BlackBoard Self-calibration package (BBS; Pandey et al. 2009), with a relatively simple initial model, containing about a dozen point sources and one shapelet model. We then used the SAGECAL package (Kazemi et al. 2011) to solve for the direction-dependent amplitude and phase variations in the data and to update the shapelet model for Cas A. To mitigate artefacts due to Cygnus A, present about 30 degrees away, we simultaneously solved for direction-dependent gains towards Cas A and Cygnus A, and subtracted the latter in the visibility data using a shapelet model. We then imaged the source using the CASA imager\(^1\) and constructed a composite sky model from the image by fitting for point and shapelet sources (see e.g., Yatawatta et al. 2011). We iterated over this scheme (BBS calibration $\rightarrow$ imaging $\rightarrow$ skymodel $\rightarrow$ calibration) to obtain high-resolution continuum images and improved source models. In Fig. 1, we present a 40 arcsec resolution continuum image of the supernova remnant at 52 MHz (single subband). Given the excellent spatial resolution of LOFAR, a number of complex features are clearly resolved (c.f., Kantharia et al. 1998; Lane et al. 2005). Further details of the calibration strategy and a full discussion of the continuum imaging of Cas A, and the wider surrounding field, will be presented in a companion paper (Yatawatta et al., in prep.).

To detect RRLs along the line-of-sight to Cas A, we calibrated the RRL visibility data sets (see Table 1) with BBS using our final sky model that was obtained from our analysis of the continuum data. Multi-channel maps were constructed using the CLEAN algorithm within CASA, and image cubes from the individual subbands were analysed separately. Spectra were then extracted over the whole remnant and over the brightest hotspot (see Fig. 1). The resultant spectra displayed a few artefacts, such as breaks at the subband boundaries and bad channels on the edge of each subband; typically around 5 per cent of the

---

channels per subband. These bad channels were removed dur-
ing further analysis. Doppler correction terms are currently not
incorporated in the LOFAR imaging pipeline, hence the spectra
were Doppler corrected after extraction. This leads to an uncer-
tainty of $\leq 1 \text{ km s}^{-1}$ in the determination of the central velocities
and line widths. This error is negligible compared to the velocity
resolution of our data.

### 3. Results

The subset of Data-1 that was used for the RRL analysis
only contained the short baselines between the core-stations
($\leq 2.6 \text{ km}$), for which Cas A is practically unresolved. Therefore,
spectra were obtained over the whole remnant with a spectral
resolution of 762 Hz channel$^{-1}$, which is equivalent to a velo-
city resolution of $\sim 5 \text{ km s}^{-1}$ at 45 MHz. We report the detection
(at $\geq 16\sigma$ level) of four carbon $\alpha$ RRLs ($\alpha$518, $\alpha$538, $\alpha$541$\alpha$
and $\alpha$543$\alpha$) towards Cas A in Data-1 between 40 to 50 MHz.
In Fig. 2, we present a representative spectrum of a RRL de-
tection, with respect to the local standard of rest (LSR). For
each detected RRL, we measured the line widths and integrated
optical depths ($\tau \nu$F) by fitting Gaussian components to the
spectra, the results of which are presented in Table 2. Only sin-
gle Gaussian-line profiles were used because our spectra do not
currently have a sufficient signal-to-noise ratio to reliably mea-
sure multiple components in the line structure. All of the de-
tected RRLs have measured velocities at $v_{\text{LSR}} \sim \pm 48 \pm 1 \text{ km s}^{-1}$,
consistent with the velocity of the gas in the Perseus arm, the
likely absorber along the line-of-sight to Cas A (Konvalenko
1984; Ershov et al. 1984, 1987; Payne et al. 1989, 1994). These
RRL detections from Data-1 represent the first spectral-line mea-
surements made with LOFAR.

The main goal of our study is to investigate whether there
is any structure in the absorbing gas by detecting a variation in
the integrated optical depths of the RRLs over the extent of
the remnant. For this, LOFAR’s unparalleled spatial resolution
at frequencies below 100 MHz is required. We extracted spec-
tra using Data-2 in two ways; one towards the compact hotspot
component and the other over the entire area of the remnant.
We detected five carbon $\alpha$ RRLs (at $> 5\sigma$ level) in both our
integrated spectra and the spectra extracted over the brightest
hotspot component in the remnant. As these lines were only
marginally resolved, we estimated their integrated optical depths
by summing the measured optical depth over two channels. The
results of these measurements are also given in Table 2. In Fig. 3,
we show a representative detection of a carbon $\alpha$ RRL ($\alpha$541$\alpha$
against the whole remnant and the hotspot. Earlier studies (see
e.g., Payne et al. 1989) reported two components at $\alpha$518$\alpha$
previously reported values despite the uncertainties in determin-
ing various parameters (see e.g., Payne et al. 1994; Gordon &
Sorochenko 2009, Sect. 3.3.6), indicating that cosmic rays can
not ionise the intercloud gas to the observed degree.

### Notes.

For the case of Data-1, the spectral resolution was sufficient
to resolve the lines and the fitted Gaussian full width at half maximum
(FWHM) is reported. For Data-2, the RRLs were not fully resolved and
so the integrated optical depths were obtained over two spectral channel
widths. The integrated optical depths have been calculated over the full
remnant (SNR) for data sets Data-1 and Data-2, and around the region
of the bright hotspot for Data-2 (see Fig. 1).
4. Discussion and conclusions

In total, we have detected five carbon $\alpha$ RRLs towards Cas A from our two LOFAR commissioning data sets. In Fig. 4, we plot the integrated optical depths of these RRLs as measured from each LOFAR data set, and also the integrated optical depths for those RRLs that were previously measured towards Cas A with other telescopes (Ershov et al. 1984, 1987; Payne et al. 1989, 1994), as a function of the principal quantum number. We see that the integrated optical depths, as measured over the whole remnant, are consistent between Data-1 and Data-2 for the four RRLs that are common to both data sets. This demonstrates the spectral stability of our LOFAR commissioning data sets. We also find consistency for the RRL C538$\alpha$ and C552$\alpha$, where we have both LOFAR and previously reported measurements in the literature. Although we currently do not have measurements for the other two previously detected RRLs (C502$\alpha$ and C552$\alpha$), the reported integrated optical depths of these lines are generally consistent with the RRLs that we have detected in the LOFAR data sets.

Multiple carbon RRLs are usually modelled together in order to derive the physical conditions of the line-absorbing gas, since the electron levels are in non-local thermal equilibrium (non-LTE) conditions. Crucial inputs to these models include accurate line width measurements from high-spectral resolution data. We also find from Fig. 4 that the integrated optical depths towards the hotspot are larger by up to almost a factor of 2, when compared to the integrated optical depths measured over the whole remnant. This shows that there is small-scale angular structure and/or the geometry of the RRL-absorbing gas is such that there is varying levels of absorption over the face of the remnant (see, e.g. Kantharia et al. 1998). This corresponds to structure in the RRL-absorbing gas of the order of ~1 pc. To model this structure, we plan to make new LOFAR observations with a higher spectral and spatial resolution in the future. Our results from the commissioning data sets demonstrate that LOFAR can be used to carry out spectral line observations at low radio frequencies. For the case of RRL studies, LOFAR will be an important tool in the future for two main reasons. First, the up to arcsecond-scale resolution that can be obtained with LOFAR, beam dilution effects will not affect our detection sensitivity. Second, due to the large observable frequency range of LOFAR, from 10 to 250 MHz, hundreds of low-frequency RRLs will be detectable for the first time. Furthermore, due to the large bandwidth that can be observed during each observation, many of these RRLs will be detected in a single observation, making wide-field surveys for RRLs possible for the first time. The results reported here form part of the LOFAR Surveys key science project. In the near future, we plan to observe various bright sources (Galactic and extragalactic) with compact morphologies in the LOFAR LBA and HBA bands. Later studies will focus on RRLs towards regions of diffuse emission in the Galactic plane and fields with complex emission features.

Acknowledgements. LOFAR, designed and constructed by ASTRON, has facilities in several countries, that are owned by various parties (each with their own funding sources), and that are collectively operated by the International LOFAR Telescope (ILT) foundation under a joint scientific policy.
