A search for squarks and gluinos in final states containing jets, missing transverse momentum and no high-$p_T$ electrons or muons is presented. The data represent the complete sample recorded in 2011 by the ATLAS experiment in 7 TeV proton-proton collisions at the Large Hadron Collider, with a total integrated luminosity of 4.7 fb$^{-1}$. No excess above the Standard Model background expectation is observed. Gluino masses below 860 GeV and squark masses below 1320 GeV are excluded at the 95% confidence level in simplified models containing only squarks of the first two generations, a gluino octet and a massless neutralino, for squark or gluino masses below 2 TeV, respectively. Squarks and gluinos with equal masses below 1410 GeV are excluded. In minimal supergravity/constrained minimal supersymmetric Standard Model models with $\tan\beta = 10$, $A_0 = 0$ and $\mu > 0$, squarks and gluinos of equal mass are excluded for masses below 1360 GeV. Constraints are also placed on the parameter space of supersymmetric models with compressed spectra. These limits considerably extend the region of supersymmetric parameter space excluded by previous measurements with the ATLAS detector.

DOI: 10.1103/PhysRevD.87.012008

**I. INTRODUCTION**

Many extensions of the Standard Model (SM) include heavy colored particles, some of which could be accessible at the Large Hadron Collider (LHC) [1]. The squarks and gluinos of supersymmetric (SUSY) theories [2–10] form one class of such particles. This paper presents a new ATLAS search for squarks and gluinos in final states containing only jets and large missing transverse momentum. Interest in this final state is motivated by the large number of $R$-parity conserving models, including minimal supergravity (MSUGRA)/constrained minimal supersymmetric Standard Model (CMSSM) scenarios [11–15], in which squarks $\tilde{q}$ and gluinos $\tilde{g}$ can be produced in pairs ($\tilde{g}\tilde{g}$, $\tilde{q}\tilde{q}$, $\tilde{g}\tilde{g}$) and can generate the final state of interest through their direct ($\tilde{q} \rightarrow q\tilde{\chi}_1^0$ and $\tilde{g} \rightarrow q\tilde{\chi}_1^0$) and cascade decays to weakly interacting neutralinos $\tilde{\chi}_1^0$, which escape the detector unseen. “Squark” here refers only to the superpartners of the four light-flavor quarks. The analysis presented here is based on a study of final states which are reconstructed as purely hadronic. Events with reconstructed electrons or muons are vetoed to avoid overlap with a related ATLAS search [16] that requires them. The term “leptons” is therefore used in this paper to refer only to reconstructed electrons and muons and does not include $\tau$ leptons. Compared to previous studies [17], this updated analysis uses the full data set (4.7 fb$^{-1}$) recorded at $\sqrt{s} = 7$ TeV in 2011 and extends the sensitivity of the search by selecting final state topologies with higher jet multiplicities. The search strategy is optimized for maximum discovery reach in the $(m_{\tilde{g}}, m_{\tilde{q}})$ plane (where $m_{\tilde{g}}$, $m_{\tilde{q}}$ are the gluino and squark masses, respectively) for a range of models. This includes a simplified model in which all other supersymmetric particles, except for the lightest neutralino, are given masses beyond the reach of the LHC. Although interpreted in terms of SUSY models, the main results of this analysis (the data and expected background event counts in the signal regions) are relevant for constraining any model of new physics that predicts the production of jets in association with missing transverse momentum.

The paper begins with a brief description of the ATLAS detector (Sec. II), followed by an overview of the analysis strategy (Sec. III). This is followed by short descriptions of the data and Monte Carlo (MC) simulation samples used (Sec. IV) and of the trigger strategy (Sec. V). Section VI describes the physics object definitions. Section VII describes the event cleaning techniques used to reject non-collision backgrounds, while Sec. VIII describes the final event selections and resulting event counts. Section IX describes the techniques used to estimate the SM backgrounds, with the systematic uncertainties summarized in Sec. X. Section XI describes the statistical model used to interpret the observations and presents the results in terms of constraints on SUSY model parameter space. Finally Sec. XII summarizes the main results and conclusions.

**II. THE ATLAS DETECTOR**

The ATLAS detector [18] is a multipurpose particle physics apparatus with a forward-backward symmetric cylindrical geometry and nearly $4\pi$ coverage in solid...
angle [19]. The layout of the detector features four superconducting magnet systems, which comprise a thin solenoid surrounding inner tracking detectors and three large toroids used in a large muon spectrometer. Located between these two detector systems, the calorimeters are of particular importance to this analysis. In the pseudorapidity region \( |\eta| < 3.2 \), high-granularity liquid-argon (LAr) electromagnetic (EM) sampling calorimeters are used. An iron/scintillator-tile calorimeter provides hadronic coverage over \( |\eta| < 1.7 \). The end-cap and forward regions, \( 1.5 < |\eta| < 4.9 \), are instrumented with LAr calorimeters for both EM and hadronic measurements.

### III. ANALYSIS STRATEGY

This analysis aims to search for the production of heavy SUSY particles decaying into jets and neutralinos, with the latter creating missing transverse momentum \( (E_T^{\text{miss}}) \). Because of the high mass scale expected for the SUSY signal, the “effective mass” \( m_{\text{eff}} \) (defined below) is a powerful discriminant between the signal and most SM backgrounds. The requirements used to select jets and leptons (which are referred to as physics objects) are chosen to give sensitivity to a broad range of SUSY models. In order to achieve maximal reach over the \( (m_{\tilde{q}}, m_{\tilde{g}}) \) plane, six analysis channels are defined. Squarks typically generate at least one jet in their decays, for instance through \( \tilde{q} \rightarrow q \tilde{\chi}_1^0 \), while gluinos typically generate at least two jets, for instance through \( \tilde{g} \rightarrow q \bar{q} \tilde{\chi}_1^0 \). Processes contributing to \( \tilde{q} \tilde{q}, \tilde{q} \tilde{g}, \tilde{g} \tilde{g} \) final states therefore lead to events containing at least two, three or four jets, respectively. Cascade decays of heavy particles, as well as initial and final state radiation, tend to further increase the final state multiplicity.

Inclusive analysis channels, labeled A–E and characterized by increasing minimum jet multiplicity from two to six, are therefore defined. In addition, the two-jet sample is divided into two channels, A and A’, using the ratio of \( E_T^{\text{miss}} \) to \( m_{\text{eff}} \), giving a total of six channels. Channel A’ is designed to improve the sensitivity to models with small supersymmetric particle ("sparticle") mass splittings, where the presence of initial state radiation jets may allow signal events to be selected irrespective of the visibility of the sparticle decay products. The lower jet multiplicity channels focus on models characterized by squark pair production with short decay chains, while those requiring high jet multiplicity are optimized for gluino pair production and/or long cascade decay chains. The final limits are set using the channel with the best expected sensitivity for each hypothesis. The channels and signal regions (SRs) are summarized in Table I. The final selection criteria are defined without reference to collision data satisfying the criteria applied earlier in the selection.

The effective mass is defined to be the scalar sum of the transverse momenta of the leading \( N \) jets in the event together with \( E_T^{\text{miss}} \):

\[
m_{\text{eff}} \equiv \sum_{i=1}^{N} p_T^{(i)} + E_T^{\text{miss}}.
\]

This general quantity is used to select events in two different ways, for which the specific values of \( N \) used in the sum differ. Criteria are placed on the ratio of \( E_T^{\text{miss}} \) to \( m_{\text{eff}} \), in which context \( N \) is defined to be the minimum number of jets used in the channel under consideration (for example \( N = 2 \) for channel A). In Table I, where the number of jets used is explicitly noted, the expression \( m_{\text{eff}} (Nj) \) indicates the exact, exclusive, number of jets used. However, the final signal selection in all channels uses criteria on a more inclusive definition, \( m_{\text{eff}} \text{(incl.)} \), for which the sum extends over all jets with \( p_T > 40 \text{ GeV} \).

Requirements on \( m_{\text{eff}} \) and \( E_{T}^{\text{miss}} \), which suppress the QCD multijet background, formed the basis of the previous ATLAS jets + \( E_{T}^{\text{miss}} \) + 0-lepton SUSY search [17]. The same strategy is adopted in this analysis.

In Table I, \( \Delta \phi (\text{jet}_i, \vec{P}_T^{\text{miss}})_{\text{min}} \) is the smallest of the azimuthal separations between the missing momentum vector in the transverse plane, \( \vec{P}_T^{\text{miss}} \), and the reconstructed jets. For channels A, \( A' \) and B, the selection requires \( \Delta \phi (\text{jet}_i, \vec{P}_T^{\text{miss}})_{\text{min}} > 0.4 \) rad using up to three leading jets. For the other channels an additional requirement \( \Delta \phi (\text{jet}_i, \vec{P}_T^{\text{miss}})_{\text{min}} > 0.2 \) rad is applied to the remaining jets with \( p_T > 40 \) GeV. Requirements on \( \Delta \phi (\text{jet}_i, \vec{P}_T^{\text{miss}})_{\text{min}} \) and \( E_{T}^{\text{miss}}/m_{\text{eff}} \) are designed to reduce the background from multijet processes.

SM background processes contribute to the event counts in the signal regions. The dominant sources are: \( W \) + jets, \( Z \) + jets, top quark pair, single top quark, diboson and multijet production. The majority of the \( W \) + jets background is composed of \( W \to \tau \nu \) events, or \( W \to e\nu, \mu \nu \) events in which no electron or muon candidate is reconstructed. The largest part of the \( Z \) + jets background comes from the irreducible component in which \( Z \to \nu \bar{\nu} \) decays generate large \( E_{T}^{\text{miss}} \). Top quark pair production followed by semileptonic decays, in particular \( t\bar{t} \to b\bar{b}q'\tau' \nu \) with the \( \tau \) lepton decaying hadronically, as well as single top quark events, can also generate large \( E_{T}^{\text{miss}} \) and pass the jet and lepton requirements at a non-negligible rate. The multijet background in the signal regions is caused by poor reconstruction of jet energies in the calorimeters leading to apparent missing transverse momentum, as well as by neutrino production in semileptonic decays of heavy quarks. Extensive validation of the MC simulation against data has been performed for each of these background sources and for a wide variety of control regions (CRs).

Each of the six channels is used to construct between one and three signal regions with “tight,” “medium” and/or “loose” \( m_{\text{eff}} \) (incl.) selections, giving a total of 11 SRs. In order to estimate the backgrounds in a consistent and robust fashion, five control regions are defined for each of the SRs, giving 55 CRs in total. Each ensemble of one SR and five CRs constitutes a different “stream” of the analysis. The CR selections are optimized to maintain adequate statistical weight, while minimizing as far as possible the systematic uncertainties arising from extrapolation to the SR, and any contamination from signal events. This is achieved by using kinematic selections that are as close as possible to the relevant SR, and making use of other event properties to create CR samples to measure the backgrounds.

The CRs are listed in Table II. CR1a and CR1b are used to estimate the contribution of \( Z \to \nu \bar{\nu} \) + jets background events to the SR by selecting samples of \( \gamma \to \ell \ell \) and \( Z(\to \ell \ell) \) + jets events, respectively. The control region CR2 uses a reversed and tightened criterion on \( \Delta \phi (\text{jet}_i, \vec{P}_T^{\text{miss}})_{\text{min}} \) for up to three selected leading jets (depending on channel) to produce a data sample enriched with multijet background events. Otherwise it uses identical kinematic selections to the SRs. CR3 and CR4 use, respectively, a \( b \)-jet veto or \( b \)-jet requirement together with a lepton + \( E_{T}^{\text{miss}} \) transverse mass (\( m_{T} \)) requirement to select samples of \( W(\to \ell \nu) \) + jets and semileptonic \( t\bar{t} \) background events. Other selections are similar to those used to select the corresponding signal region, although in CR1b, CR3 and CR4 the requirements on \( \Delta \phi (\text{jet}_i, \vec{P}_T^{\text{miss}})_{\text{min}} \) and \( E_{T}^{\text{miss}}/m_{\text{eff}} \) are omitted to maximize the number of events without introducing extrapolations in energy or jet multiplicity.

The observed numbers of events in the CRs for each SR are used to generate internally consistent SM background estimates for the SR via a likelihood fit. This procedure enables CR correlations and contamination of the CRs by other SM processes and/or SUSY signal events to be taken into account. The same fit also allows the statistical significance of the observation in the SR with respect to the SM expectation to be determined. The estimated number of background events for a given process, \( N(\text{SR, scaled}) \), is given by

\[
N(\text{SR, scaled}) = N(\text{CR, obs}) \times \left[ \frac{N(\text{SR, unscaled})}{N(\text{CR, unscaled})} \right],
\]

where \( N(\text{CR, obs}) \) is the observed number of data events in the CR for the process, and \( N(\text{SR, unscaled}) \) and \( N(\text{CR, unscaled}) \) are estimates of the contributions from the process to the SR and CR, respectively, as described in Sec. IX. The ratio appearing in the square brackets in

Eq. (2) is defined to be the transfer factor (TF). Similar equations containing inter-CR TFs enable the background estimates to be normalized coherently across all the CRs. The likelihood fit adjusts the predicted background components in the CRs and SRs using the TFs and the unscaled CR event counts as constraints, taking into account their uncertainties. The scaled values are output from the fit.

The likelihood function for observing \( n \) events in one of the channels (A–E, loose to tight) is the product of Poisson distributions, one for the signal region and one for each of the main control regions constraining the \( Z + \) jets (CR1a/b), multijets (CR2), \( W + \) jets (CR3) and \( t\bar{t} \) (CR4) contributions, labeled \( P_{SR} \), \( P_{ZRa,b} \), \( P_{IR} \), \( P_{WR} \) and \( P_{TR} \), respectively, and of the parton distribution functions (PDFs) constraining the systematic uncertainties \( C_{\text{Sys}} \):

\[
L(n|\mu, b, \theta) = P_{SR} \cdot P_{ZRa,b} \cdot P_{IR} \cdot P_{WR} \cdot P_{TR} \cdot C_{\text{Sys}}(\theta).
\]

(3)

The total expected background is \( b \). The expected means for the Poisson distributions are computed from the observed numbers of events in the control regions, using the TFs. The signal strength \( \mu \) parameterizes the expected signal, with \( \mu = 1 \) giving the full signal expected in a given model. The nuisance parameters (\( \theta \)) parameterize the systematic uncertainties, such as that on the integrated luminosity.

The expected number of events in the signal region is denoted by \( \lambda_S \), while \( \lambda_i \) denotes the expected number of events in control region \( i \). These are expressed in terms of the fit parameters \( \mu \) and \( b \) and an extrapolation matrix \( C \) (connecting background and signal regions) as follows:

\[
\lambda_S(\mu, b, \theta) = \mu \cdot C_{SR\rightarrow SR}(\theta) \cdot s + \sum_j C_{jR\rightarrow SR}(\theta) \cdot b_j,
\]

(4)

\[
\lambda_i(\mu, b, \theta) = \mu \cdot C_{SR\rightarrow IR}(\theta) \cdot s + \sum_j C_{jR\rightarrow IR}(\theta) \cdot b_j,
\]

(5)

where the index \( j \) runs over the background control regions. The observed number of signal events in the SR(CR\_IR) is \( s(b_j) \), respectively. The diagonal elements of the matrix are all unity by construction. The off-diagonal elements are the various TFs.

This background estimation procedure requires the determination of the central expected values of the TFs for each SM process, together with their associated correlated and uncorrelated uncertainties, as described in Sec. IX. The multijet TFs are estimated using a data-driven technique, which applies a resolution function to well-measured multijet events in order to estimate the effect of mismeasurement on \( E_T^{\text{miss}} \) and other variables. The other TF estimates use fully simulated MC samples validated with data (see Sec. IV B). Some systematic uncertainties, for instance those arising from the jet energy scale (JES), or theoretical uncertainties in MC simulation cross sections, largely cancel when calculating the event count ratios constituting the TFs.

The result of the likelihood fit for each stream includes a set of background estimates and uncertainties for the SR together with a \( p \) value giving the probability for the hypothesis that the observed SR event count is compatible with background alone. Conservative assumptions are made about the migration of SUSY signal events between regions. When seeking an excess due to a signal in a particular SR, it is assumed that the signal contributes only to the SR; i.e. the SUSY TFs are all set to zero, giving no contribution from signal in the CRs. If no excess is observed, then limits are set within specific SUSY parameter spaces, taking into account theoretical and experimental uncertainties on the SUSY production cross section and kinematic distributions. Exclusion limits are obtained using a likelihood test. This compares the observed event rates in the signal regions with the fitted background expectation and expected signal contributions, for various signal hypotheses. Since the signal hypothesis for any specific model predicts the SUSY TFs, these exclusion limits do allow for signal contamination in the CRs.

IV. DATA AND SIMULATED SAMPLES

A. Proton-proton collision-data sample

The data used in this analysis were taken in 2011 with the LHC operating at a center-of-mass energy of 7 TeV. Over this period the peak instantaneous luminosity increased from \( 1.3 \times 10^{30} \) to \( 3.7 \times 10^{33} \text{ cm}^{-2} \text{ s}^{-1} \) and the peak mean number of interactions per bunch crossing increased from 2 to 12. Application of beam, detector and data-quality requirements resulted in a total integrated luminosity of 4.7 \( \text{fb}^{-1} \) [20,21]. The precision of the luminosity measurement is 3.9\%. The trigger used is described in Sec. V.

B. Monte Carlo samples

MC samples are used to develop the analysis, optimize the selections, determine the transfer factors used to estimate the \( W + \) jets, \( Z + \) jets and top quark production backgrounds, and to assess sensitivity to specific SUSY signal models. Samples of simulated multijet events are generated with PHOJET [22], using the MRST2007LO* modified leading-order PDFs [23], for use in the data-driven background estimates. Production of top quark pairs, including accompanying jets, is simulated with ALPGEN [24] and the CTEQ6L1 [25] PDF set, with a top quark mass of 172.5 GeV. Samples of \( W \) and \( Z/\gamma^* \) events with accompanying jets are also produced with ALPGEN. Diboson \((WW, WZ, ZZ, W\gamma^*)\) production is simulated with SHERPA [26]. Single top quark production is simulated with ACERMC [27]. Fragmentation and hadronization for the ALPGEN samples is performed with HERWIG [28,29], using JIMMY [30] for the underlying event. For the \( \gamma^* + \text{jet} \) estimates of the \( Z(\rightarrow \nu\bar{\nu}) + \text{jets} \) backgrounds, photon and
Z events are also both produced using SHERPA for consistency checks of the ALPGEN results. SUSY signal samples are generated with HERWIG++ [31] or MADGRAPH/PYTHIA6 [22,32,33]. Signal cross sections are calculated to next-to-leading order in the strong coupling constant, including the resummation of soft gluon emission at next-to-leading-logarithmic accuracy (NLO + NLL) [34–39]. The nominal cross section and the uncertainty are taken from an ensemble of cross section predictions using different PDF sets and factorization and renormalization scales, as described in Ref. [40].

The MC samples are generated using the same parameter set as Refs. [41–43] and passed through the ATLAS detector simulation [44] based on GEANT4 [45]. Differing pileup (multiple proton-proton interactions in a given event) conditions as a function of the LHC instantaneous luminosity are taken into account by overlaying simulated minimum-bias events onto the hard-scattering process and reweighting them according to the expected mean number of interactions per LHC bunch crossing.

V. TRIGGER SELECTIONS

The baseline triggers for the signal region event selection in the 2011 analysis use jets and $E_T^{\text{miss}}$ [46,47]. The jet and $E_T^{\text{miss}}$ trigger required events to contain a leading jet with a transverse momentum ($p_T$), measured at the electromagnetic energy scale [48], above 75 GeV and significant missing transverse momentum. The detailed trigger specification, including the value of the $E_T^{\text{miss}}$ threshold, varied throughout the data-taking period, partly as a consequence of the rapidly increasing LHC instantaneous luminosity. The trigger threshold on the missing transverse momentum increased from 45 GeV at the start of the data-taking period to 55 GeV at the end. The trigger reached its full efficiency of > 98% for events with a reconstructed jet with $p_T$ exceeding 130 GeV and more than 160 GeV of missing transverse momentum. Trigger efficiencies are extracted using a sample selected by a looser trigger, taking into account correlations, i.e. correcting for the efficiency of the looser trigger. Prescaled single-jet triggers, which acquired fixed fractions of the data, are used for the trigger efficiency study.

A second study verifies that the efficiency of the baseline trigger becomes maximal at the values quoted above. The efficiencies are determined with an independent sample of events expected to possess $E_T^{\text{miss}}$ generated by neutrinos. A sample triggered by electron candidates is used, where jets from electrons reconstructed with tight selection criteria are discarded. This trigger selected mostly $W \rightarrow e\nu$ events with jets and ran unprescaled, thus providing a large number of events.

VI. OBJECT RECONSTRUCTION

The event reconstruction algorithms create the physics objects used in this analysis: electrons, muons, jets, photons and $b$ jets. Once these objects are defined, the overall missing transverse momentum can be calculated. A failure in the calorimeter electronics created a small dead region ($0 < \eta < 1.4, -0.8 < \phi < -0.6$) in the second and third layers of the electromagnetic calorimeter, which affected energy measurements in about 20% of the data sample. Any event with a jet that is inside the affected region and that is expected on the basis of shower shape to potentially contribute significantly to the $E_T^{\text{miss}}$ is removed from the sample to avoid fake signals [49]. The energies of jets inside the affected region which are not expected to create $E_T^{\text{miss}}$ are corrected using the functioning calorimeter layers.

Jet candidates are reconstructed using the anti-$k_T$, jet clustering algorithm [50,51] with a radius parameter of 0.4. The inputs to this algorithm are clusters [52] of calorimeter cells seeded by those with energy significantly above the measured noise. Jet momenta are constructed by performing a four-vector sum over these cell clusters, measured at the electromagnetic scale, treating each as an $(E, \vec{p})$ four-vector with zero mass. The jet energies are corrected for the effects of calorimeter noncompensation and inhomogeneities by using $p_T$- and $\eta$-dependent calibration factors derived from MC simulation and validated with extensive test-beam and collision-data studies [53]. Only jet candidates with $p_T > 20$ GeV are subsequently retained.

Electron candidates are required to have $p_T > 20$ GeV and $|\eta| < 2.47$ and to pass the “medium” electron shower shape and track selection criteria described in Ref. [54]. Muon candidates [55,56] are required to have matching tracks in the inner detector and muon spectrometer with $p_T > 10$ GeV and $|\eta| < 2.4$.

Following the steps above, overlaps between candidate jets with $|\eta| < 2.8$ and leptons are resolved as follows: first, any such jet candidate lying within a distance $\Delta R = \sqrt{\Delta\eta^2 + (\Delta\phi)^2} = 0.2$ ($\phi$ measured in radians) of an electron is discarded; then any lepton candidate remaining within a distance $\Delta R = 0.4$ of any surviving jet candidate is discarded. The first requirement prevents energy deposits from being interpreted as both jets and electrons. The second ensures that leptons produced within jets are not used to veto the event during the selection described in Sec. VIII.

The measurement of the missing transverse momentum two-vector $\vec{P}_T^{\text{miss}}$ is based on the transverse momenta of all remaining jet and lepton candidates and all calorimeter clusters not associated with such objects. Following this step, all jet candidates with $|\eta| > 2.8$ are discarded, owing to their lower precision. Thereafter, the remaining lepton and jet candidates are considered “reconstructed,” and the term “candidate” is dropped.

Photons are identified with the same selection criteria as used in the ATLAS prompt photon cross section analysis [57], where an isolated photon passing the tight photon identification criteria is required. Jets are classified as $b$ jets...
using a neural network algorithm, which takes as inputs the impact parameter measurements and the topological structure of b-quark decays, as described in Refs. [58,59].

VII. REMOVAL OF NONCOLLISION BACKGROUNDS

Noncollision backgrounds are produced predominantly by noise sources in the calorimeters, cosmic ray events and beam collisions with residual gas in the beam pipe (beam-gas events). The requirement of a vertex near the nominal interaction point with at least five associated tracks is effective at suppressing these backgrounds. Further criteria are applied which require that the fractional energy deposited in each calorimeter layer, and in any cells with known quality problems, is consistent with that expected from beam-beam events. In addition, the energy observed in charged particle tracks associated with the calorimeter cluster and the timing of the energy depositions in calorimeter cells with respect to the beam-crossing time are checked [53]. Following these selections, the remaining background is estimated by using the observed time distribution of the leading jets with respect to the bunch crossing, to create a background dominated control region. The noncollision background is found to be negligible in all of the SRs and CRs used.

VIII. EVENT SELECTION

Following the object reconstruction and event cleaning described above, a lepton veto is applied to reject \( W(\rightarrow \ell \nu) + \) jets and leptonic \( t\bar{t} \) events in which neutrinos generate the \( E_{T}^{miss} \) signature. The lepton \( p_T \) threshold used in the veto is set at 20 (10) GeV for electrons (muons) to ensure that selected events correspond to a phase-space region in which the veto efficiency is well understood.

### TABLE III. Observed numbers of events in data and fitted background components in each SR. For the total background estimates, the quoted uncertainties give the statistical (MC simulation and CR combined) and systematic uncertainties, respectively. For the individual background components, the total uncertainties are given, while the values in parenthesis indicate the prefit predictions. The predictions for \( W + \) jets, \( Z + \) jets and \( t\bar{t} \) plus single top quark are from ALPGEN and are normalized to luminosity. In the case of the multijet background, the prefit values are from the data-driven method, normalized at low mass. The diboson background is estimated with MC simulation normalized to luminosity. The values give the probability of the observation being consistent with the estimated background, and the “Gauss. \( \sigma \)” values give the number of standard deviations in a Gaussian approximation, evaluated for a single observation at a time. The last two rows show the upper limits on the excess number of events, and the excess cross section, above that expected from the SM. The observed upper limit is followed in brackets by the expected limit, with the super- and subscripts showing the expectation from \( \pm 1 \sigma \) changes in the background (denoted by \( \dagger \) and \( \ddagger \), respectively).

</table>
The signal regions are then defined by the kinematic selections given in Table I. Requirements on the transverse momenta of additional jets select inclusive 2-, 3-, 4-, 5- and 6-jet events in channels A/A', B, C, D and E, respectively. The jet $p_T$ thresholds for the leading up to four jets are set at 60 GeV in order to minimize the impact of pileup on selection efficiency and improve background rejection.

Removing events with a small angle in the transverse plane ($\Delta \phi$) between jets and $E_T^{miss}$ suppresses multijet background in which mismeasurement of jet energy generates fake missing transverse momentum along the jet direction. For channels A, A' and B a requirement $\Delta \phi > 0.4$ radians is applied to the leading (up to) three selected jets with $p_T > 40$ GeV, before the final SR selection, to minimize loss of signal efficiency. For the other channels this requirement is augmented by a looser requirement that the $E_T^{miss}$ exceeds a specific fraction of the effective

FIG. 1 (color online). Observed $m_{\text{eff (incl.)}}$ distribution for channel A. In the top panel, the histograms show the SM background expectations, both before (black open histogram) and after [medium (red) open histogram] use of a fit to scale the expectations to CR observations. This fit is applied to illustrate the SR + CR fitting technique used in the main analysis. Before scaling, the MC simulation expectations are normalized to luminosity. The multijet background is estimated using the jet smearing method described in the text. After scaling, the $W +$ jets, $Z +$ jets and $t\bar{t}$ and single top quark and multijet distributions (denoted by full histograms) are normalized to data in corresponding control regions over the full $m_{\text{eff}}$ range. Two MSUGRA/CMSSM benchmark model points with $m_0 = 500$ GeV, $m_{1/2} = 570$ GeV, $A_0 = 0$, $\tan \beta = 10$ and $\mu > 0$ and with $m_0 = 2500$ GeV, $m_{1/2} = 270$ GeV, $A_0 = 0$, $\tan \beta = 10$ and $\mu > 0$, illustrating different topologies, are also shown. These points lie just beyond the reach of the previous analysis [17]. The arrows indicate the locations of the lower edges of the two signal regions. The bottom panel shows the fractional deviation of the data from the total unscaled background estimate (black points), together with the fractional deviation of the total scaled background estimate from the total unscaled background estimate [medium (red) line]. The light (yellow) band shows the combined experimental uncertainties on the unscaled background estimates from jet energy scale, jet energy resolution, the effect of pileup, the treatment of energy outside of reconstructed jets and MC simulation sample size. The medium (green) band includes also the total theoretical uncertainties.

FIG. 2 (color online). Observed $m_{\text{eff (incl.)}}$ distribution for channel A', as for Fig. 1.

FIG. 3 (color online). Observed $m_{\text{eff (incl.)}}$ distribution for channel B, as for Fig. 1.
The multijet cross section is also suppressed at higher jet multiplicities, allowing the \( E_T^{\text{miss}} \) requirement to be loosened.

Finally, the signal regions are defined by criteria on \( m_{\text{eff}}(\text{incl.}) \) which select events with hard kinematics in order to provide strong suppression of all SM background processes. Up to three \( m_{\text{eff}}(\text{incl.}) \) values are specified per channel, corresponding to distinct signal regions tight, medium and loose, in which the final event samples are counted.

Table III lists the number of data events passing each of the SR selections. The distributions of \( m_{\text{eff}}(\text{incl.}) \) [prior to the final \( m_{\text{eff}}(\text{incl.}) \) selections] for each channel for data and SM backgrounds are shown in Figs. 1–6. Details of the CR selections, and the methods used to obtain the background estimates follow in Sec. IX. The information is used in Sec. XI to produce the final results.

IX. BACKGROUND ESTIMATION

A. Introduction

The \( Z(\rightarrow \nu \bar{\nu}) + \text{jets} \) process constitutes the dominant irreducible background in this analysis. It is estimated using control regions enriched in related processes with similar kinematics: events with isolated photons and jets [60] (CR1a, Sec. IX B) and \( Z(\rightarrow ee/\mu\mu) + \text{jets} \) events (CR1b, Sec. IX C). The reconstructed momentum of the photon or the lepton-pair system is added to \( \hat{E}_T^{\text{miss}} \) to obtain an estimate of the \( E_T^{\text{miss}} \) observed in \( Z(\rightarrow \nu \bar{\nu}) + \text{jets} \) events. The predictions from both control regions are found to be in good agreement, and both are used in the final fit. The small additional background contributions from \( Z(\rightarrow ee/\mu\mu/\tau\tau) \) decays in which the leptons are misidentified or unreconstructed, and from misidentified photon events, are estimated using the same control regions.
with appropriate transfer factors. The TF for CR1a estimates $Z(\rightarrow \nu \bar{\nu}) + \text{jets}$ in the SR and is corrected to give an estimate of $Z + \text{jets}$ in the SR by multiplying by the ratio of $Z + \text{jets}$ events to $Z(\rightarrow \nu \bar{\nu}) + \text{jets}$ events derived from MC simulation. In the case of CR1b the TF is calculated between $Z(\rightarrow ee/\mu\mu/\tau\tau) + \text{jets}$ in the CR and $Z(\rightarrow \nu \bar{\nu}/ee/\mu\mu/\tau\tau) + \text{jets}$ in the SR. Thus both methods ultimately provide an estimate of the total $Z + \text{jets}$ background in the SR.

The backgrounds from multijet processes are estimated using a data-driven technique based upon the convolution of jets in a low $E_T^{\text{miss}}$ data sample with jet response functions derived from multijet dominated data control regions (Sec. IX D). Those from $W + \text{jets}$ and top quark processes are derived from MC simulation (Sec. IX E).

For each event a likelihood fit is performed to the observed event counts in the five CRs, taking into account correlations in the systematic uncertainties in the transfer factors.

B. $Z + \text{jets}$ estimate using a $\gamma + \text{jets}$ control region

The magnitude of the irreducible background from $Z(\rightarrow \nu \bar{\nu}) + \text{jets}$ in the SRs can be estimated using $\gamma + \text{jets}$ data. When the vector boson $p_T$ is large, as required by the SR selections, the $Z$ and $\gamma$ cross sections differ mainly by their coupling constants with respect to quarks. For this reason the cross section ratio

$$R_{Z/\gamma} = \frac{d\sigma(Z + \text{jets})/dp_T}{d\sigma(\gamma + \text{jets})/dp_T}$$

(6)

can be used to translate the observed number of photon events in the CR into an estimate of the number of $Z$ events in the SR, taking into account the leptonic branching ratios of the $Z$ and other effects. The ratio is expected to be robust with respect to both theoretical uncertainties and experimental effects, related to, for example, jet reconstruction, which would be similar for both processes and therefore cancel in the ratio.

The method uses photon events which are selected in two steps. The first aims to select a photon event sample where the efficiency and the background contamination are well known. The SR selections are then applied to these photon events, having added the photon $p_T$ to the $E_T^{\text{miss}}$ of the event to reproduce the $E_T^{\text{miss}}$ observed in $Z(\rightarrow \nu \bar{\nu})$ background events. The SR selections consist primarily of requirements on the jets and $E_T^{\text{miss}}$ in the event, which directly or indirectly, due to the $p_T$ recoil, impose kinematic constraints on the vector boson, i.e. the $Z$ or photon.

Photon events are selected by requiring at least one isolated photon passing the photon identification criteria discussed above. The photon trigger has an efficiency close to 100% for selected events with a photon $p_T \gtrsim 85$ GeV. The photons are required to lie within the fiducial region $|\eta| < 1.37$ and $1.52 < |\eta| < 2.37$. After this first photon event selection a total of 2.8 M photon candidates are obtained from the complete data set, with an estimated purity $>95\%$. Figure 7(a) shows the leading photon $p_T$ distribution for events passing the first photon selection.

In the second selection step, the SR selection criteria from Table 1 are applied to the photon sample. In order to prevent the reconstructed photon in the event from also being reconstructed as a jet, jets within $\Delta R = 0.2$ of the photon are removed. The photon $p_T$ is added to the $E_T^{\text{miss}}$ vectorial sum when applying the SR selections, using the appropriate calibration for the electromagnetic character of the photon shower.

![Figure 7](color online). Leading photon $p_T$ distribution from data and MC simulation (a) directly after the photon selection and (b) in CR1a for SR-A medium that requires $m_{\text{eff}} > 1400$ GeV. The bottom panel shows the ratio of data to MC expectation, with the light (yellow) band indicating the uncertainty.
The numbers of photon candidates which are selected by the CR1a criteria for channels A–E are presented in Table IV together with the numbers expected from MC simulation. Figure 7(b) shows the leading photon $p_T$ distribution for events in CR1a for SR-A medium, that requires $m_{\text{eff}} > 1400$ GeV. Good agreement is seen between the data and the MC simulation.

These numbers of photons are corrected for experimental effects as described in Ref. [57] before being used to estimate the TFs. The following effects are considered. The combined identification and reconstruction efficiency is estimated to be 86%, with an uncertainty of less than 1%. The identification inefficiency is dominated by the tight photon identification requirements and decreases with increasing photon $p_T$. A further uncertainty of 5% is included to account for differences in efficiency of the photon isolation criteria in different event samples. Backgrounds from multijet processes and $W +$ jets events where an electron from the W decay is misidentified as a photon are each estimated to be $\sim 1\%$ for $p_T > 200$ GeV. Therefore the background is neglected, but an uncertainty of 5% is assigned.

The number of photon events selected by the CR1a criteria is used to estimate the expected number of $Z(\to \nu\bar{\nu})$ events in the corresponding SR using

$$N_{Z(\to \nu\bar{\nu})}(p_T) = N^\gamma(p_T) \cdot \left(1 - f_{\text{fake}}\right) \cdot \varepsilon^\gamma(p_T) \cdot A^\gamma(p_T) \cdot R_{Z/\gamma}(p_T) \cdot Br(Z \to \nu\bar{\nu})$$

Here $N_{Z(\to \nu\bar{\nu})}(p_T)$ represents the number of photon candidate events passing the CR1a selections, binned in $p_T$ as in Fig. 7(b), $f_{\text{fake}}$ the fraction of fake photons in the control region, $\varepsilon^\gamma(p_T)$ the efficiency for selecting the photons and $A^\gamma(p_T)$ the photon acceptance. The cross section ratio $R_{Z/\gamma}(p_T)$ is determined from MC simulation. The uncertainties related to the cross section ratio have been studied using the two MC programs PYTHIA6 [61] and GAMBOSS (an adaptation of the VECBOS program [60,62]) and many of the theoretical uncertainties, such as the choice of scales and parton distribution functions, are found to cancel in the ratio, to a large extent [60]. It has, however, been shown that the ratio retains slight sensitivity to the jet selection and that multiparton matrix elements must be used to describe correctly all the relevant amplitudes. The final uncertainties on $R_{Z/\gamma}(p_T)$ should therefore be small, but a

---

**Table V.** Summary of transfer factors from the main control regions of each background component in every stream. In CR4 for signal regions A tight and B tight the $m_{\text{eff}}$ requirements were relaxed to 1500 GeV to increase the numbers of events in the CRs for the minor $t\bar{t}$ background.
The irreducible background from $Z \rightarrow \nu \bar{\nu}$ + jets can also be estimated independently using the observed leptonic $Z$ decays. The CR1b control regions are defined by requiring two opposite-sign electrons or muons with $p_T > 20$ GeV. In addition, the $p_T$ of the leading electron is required to be above 25 GeV to protect against trigger turn-on effects. The dilepton invariant mass must lie in the range $66 \text{ GeV} < m(\ell \ell) < 116 \text{ GeV}$. The $E_T^{\text{miss}}$ variable in the SR selection is emulated with the vectorial sum of the reconstructed $Z$ boson momentum vector and the measured $\vec{p}_T^{\text{miss}}$. The SR jet and $E_T^{\text{miss}}$ requirements are applied, without selections on $\Delta \phi(\text{jet}_i, \vec{p}_T^{\text{miss}})_{\text{min}}$ or $E_T^{\text{miss}}/m_{\text{eff}}$. These changes are made to increase the acceptance, since the precision of the method is limited by the rate of dilepton events.

In order to calculate the transfer factors, ALPGEN is used to estimate the number of $Z + \text{jets}$ events in each SR and the number of $Z \rightarrow \nu \bar{\nu}$ + jets events in each corresponding CR1b control region. The uncertainties arise from the number of MC simulation events, the jet energy scale and resolution, the electron and muon energy resolutions, the electron and muon selection efficiencies, the electron trigger efficiency, the electron energy scale, energy included in calorimeter clusters that is not associated with physics objects, the input PDFs, the modeling of pileup in the simulation, and the luminosity.

The transfer factors themselves are listed in Table V and take into account the contribution from leptonic $Z \rightarrow \tau \tau$ + jets events in CR1b. The estimated numbers of $Z + \text{jets}$ events obtained using this technique are consistent with those estimated using $\gamma + \text{jets}$ events observed in CR1a.

### D. Multijet background estimation

The probability for multijet events to pass any of the SR selection cuts used in this analysis is, by design, very small. However, the large cross section for this process could potentially compensate for the low acceptance and hence lead to significant SR contamination. These two effects also limit the applicability of conventional MC simulation techniques; firstly because very large MC data samples are required and secondly because accurate modeling of the acceptance requires exceptionally detailed understanding of the performance of every component of the calorimeters. For this reason a data-driven method is used to estimate the multijet background in the SRs. The method makes use of high-statistics samples of well-measured data multijet events to minimize statistical uncertainties. In order to determine the acceptance of the SRs for poorly measured multijet events, the jets in these events are convoluted with a function modeling the response of the calorimeters. This response function is based upon the results of MC simulations but is modified in such a way as to give good agreement between multijet estimates and data in two additional dedicated analyses. This procedure minimizes the susceptibility of the multijet background estimates in the main analysis to systematic uncertainties arising from the Monte Carlo modeling of the initial response function.

The jet response function quantifies the probability of fluctuation of the measured $p_T$ of jets and takes into account both the effects of jet misidentification and contributions from neutrinos and muons in jets from heavy flavor decays. This function is convoluted with the four-vectors of jets in low-$E_T^{\text{miss}}$ multijet data events, generating higher $E_T^{\text{miss}}$ events. These are referred to as “pseudodata” and are used to provide a minimally MC simulation dependent estimate of multijet distributions, including the distribution of $\Delta \phi(\text{jet}_i, \vec{p}_T^{\text{miss}})_{\text{min}}$ for high $m_{\text{eff}}$ events. These distributions can be used to determine the transfer factors from the low $\Delta \phi(\text{jet}_i, \vec{p}_T^{\text{miss}})_{\text{min}}$ multijet control regions CR2 to the higher $\Delta \phi(\text{jet}_i, \vec{p}_T^{\text{miss}})_{\text{min}}$ signal regions.

The method, referred to as the “jet smearing method” below, proceeds in four steps:

1. Selection of low-$E_T^{\text{miss}}$ seed events in the data. The jets in these events are well measured. These events are used in steps (3) and (4).
2. As a starting point the response function is determined in MC simulated data by comparing generator-level jet energy to reconstructed detector-level jet energy.
3. Jets in the seed events are convoluted with the response function to generate pseudodata events. The consistency between pseudodata and experimental data in two analyses (see below) is then determined. The response function is modified and the convolution repeated until good agreement is obtained.
4. Jets in the seed events are convoluted with the resulting data-constrained response function to obtain a final sample of pseudodata events. This sample is used to estimate the distributions of variables defining the control and signal regions used in the main analysis.

Seed events are triggered using single-jet triggers and offline thresholds of 50, 100, 130, 165, 200, 260 and 335 GeV are then applied. To ensure that the events contain only well-measured jets, the $E_T^{\text{miss}}$ significance (defined as $E_T^{\text{miss}}/\sqrt{E_T^{\text{sum}}}$, where $E_T^{\text{sum}}$ is the scalar sum of the transverse...
energy measured in the calorimeters) is required to be <0.6 GeV$^{1/2}$.

The response function is initially estimated from MC simulation by matching “truth” jets reconstructed from generator-level particles to detector-level jets with $\Delta R < 0.1$ in multijet samples. The four-momenta of any generator-level neutrinos in the truth jet cone are added to the four-momentum of the truth jet. Truth jets are isolated from other truth jets by $\Delta R > 0.6$. The response is the ratio of the reconstructed detector-level to generator-level jet transverse energy.

A “smeared” event is generated by multiplying each jet four-momentum in a seed event by a random number drawn from the response function. The smeared event $E_T^{\text{miss}}$ is computed using the smeared transverse momenta of the jets. The response function measured using MC

---

FIG. 8 (color online). Distributions of $R_2$ in four bins (a–d) of $|\eta|$ of the poorly reconstructed jet, for estimated true jet $p_T$, defined as $|p_T^J + P_T^{\text{miss}}|$, greater than 100 GeV. The black points represent collision data while the open medium (red) histogram represents the combined prediction. The jet smearing method described in the text is used to estimate the multijet contribution (referred to in the plots as pseudodata) while MC simulation predictions are used for the other background components. The lower panels show the fractional deviation of the data from the prediction (black points), with the light (yellow) bands showing the multijet uncertainty combined with the MC simulation statistical uncertainty on the nonmultijet estimate.
simulation is modified using additional Gaussian smearing to widen the jet response, and a correction is applied to the low-side response tail to adjust its shape. These corrections improve the agreement with the data in step (3).

Two dedicated analyses are used to constrain the shape of the jet response function in step (3). The first uses the $p_T$ asymmetry of dijet events. Events with two jets with $|\eta| < 2.8$ and $p_T > 70, 50$ GeV are selected, where there are no additional jets with $|\eta| < 2.8$ and $p_T > 40$ GeV. Events are vetoed if they contain any jet with $p_T > 20$ GeV and $\eta > 2.8$. The $p_T$ asymmetry is given by

$$A(p_{T,1}, p_{T,2}) = \frac{p_{T,1} - p_{T,2}}{p_{T,1} + p_{T,2}},$$

where the indices correspond to the jet $p_T$ ordering. This distribution is sensitive to the Gaussian response of the jets and to any non-Gaussian tails. A fit of pseudodata to the collision-data asymmetry distribution is used to adjust the response function generating the pseudodata.

A second analysis studies the $R_2$ distribution of $\approx 3$-jet events where topological selections ensure that one jet is unambiguously associated in $\phi$ with the $E_T^{miss}$ in the event. The response of the detector to this jet is then given approximately by the quantity $R_2$ defined by

$$R_2 = \frac{\bar{p}_T^1 \cdot (\bar{p}_T^1 + \bar{p}_T^{miss})}{|\bar{p}_T^1 + \bar{p}_T^{miss}|^2},$$

where $\bar{p}_T^1$ is understood to be the reconstructed $p_T$ of the jet associated with the $E_T^{miss}$. This distribution is sensitive to the tails of the response function from mismeasured jets. When the $p_T$ of the jet is undermeasured, $\bar{p}_T^{miss}$ lies parallel to $\bar{p}_T^1$ and hence $R_2 < 1$. Conversely, when the $p_T$ of the jet is overmeasured, $\bar{p}_T^{miss}$ lies antiparallel to $\bar{p}_T^1$ and hence $R_2 > 1$. Fits are performed in $p_T$ and $\eta$ bins in order to constrain the parameters describing the low-side response function tail, which affects primarily the region with $R_2 \ll 1$.

The $R_2$ distribution provides a sensitive test of the response function and hence of the background estimate in different regions of the detector, such as the transition between the barrel and end-cap calorimeters, where the energy resolution is degraded by the presence of dead material. The data are divided into four regions according to the $\eta$ of the poorly reconstructed jet associated with the $E_T^{miss}$ shown in Fig. 8. The estimates agree well, with the data indicating that non-Gaussian fluctuations are not strongly $\eta$ dependent. Given the good agreement observed between the data and estimates, no uncertainty is associated.

---

**FIG. 9** (color online). Comparison of observed and predicted distributions of $\Delta \phi(\text{jet}, \bar{p}_T^{miss})_{\text{min}}$ for the leading three jets $[\Delta \phi(\text{jet}, \bar{p}_T^{miss})_{\text{min}} (i = \{1, 2, 3\})]$, (a) after all selections except for those on $\Delta \phi(\text{jet}, \bar{p}_T^{miss})_{\text{min}}$ and $E_T^{miss}$ for signal region C loose. The histograms show the MC simulation estimates of each background component. The medium (maroon) triangles show the multijet estimates from the jet smearing technique, normalized in the regions with $\Delta \phi(\text{jet}, \bar{p}_T^{miss})_{\text{min}} (i = \{1, 2, 3\}) < 0.2 \text{ rad}$, which replaces the multijet MC simulation estimate (denoted with a histogram) in the main analysis. The hatched region denotes the total uncertainty on the multijet estimate including statistical uncertainties from the seed event sample and the smearing procedure, systematic uncertainties in the jet response function, and bias in the seed event selection. The lower panels show the fractional deviation of the data from the prediction (black points), with the light (yellow) bands showing the multijet uncertainty combined with the MC simulation statistical uncertainty on the nonmultijet estimate.
with the $\eta$ dependence of the response. Following this procedure, a good estimate of the jet response function, including non-Gaussian tails, is obtained.

In order to illustrate the technique, Fig. 9 shows comparisons between SM MC simulation predictions, data and the jet smearing estimate for distributions of $\Delta \phi (\text{jet}, \vec{P}_{T}^{\text{miss}})_{\text{min}}$ calculated with just the leading three jets. The figure makes use of the earlier stages of the event selections for SR-C loose and its associated multijet control region. The final event selections used in the analysis impose further requirements on $\Delta \phi (\text{jet}, \vec{P}_{T}^{\text{miss}})_{\text{min}}$ for additional jets with $p_T > 40 \text{ GeV}$ (see Table I). Good agreement is seen in Fig. 9 both between the data and MC simulation and between the data and the smearing estimate.

In order to check that the above method is robust against changes in pileup conditions, which changed significantly during data taking, the method was repeated with the data divided into subsamples corresponding to four time periods representative of different pileup regimes. No significant dependence upon the level of pileup was found.

The resulting multijet transfer factors between CR2 and SR for the signal regions are shown in Table V. Several corrections are applied to MC simulation events:

- (i) Each event in the CR is weighted by the ratio of the lepton identification efficiency in data to that in simulation. Similarly, the numbers in the signal region are weighted by a corresponding inefficiency scale factor. This weighting is performed on an event-by-event basis, based on the simulated lepton’s transverse momentum and pseudorapidity.
- (ii) A similar scale factor is applied for the $b$-tagging efficiency (CR4) and fake rate (CR3), which differ between data and simulation [58,59]. This is also performed as an event-by-event weighting.
- (iii) The leptons are smeared such that their energy resolution reflects that measured in data.

Various sources of systematic uncertainty on the transfer factors have been considered. For the leptons, the identification efficiency, energy resolution and trigger efficiency are considered. The $b$-tagging efficiency and fake rate, jet energy scale and jet energy resolution (for both $b$-quark and light jets separately), are considered, together with the effect of pileup, of calorimeter electronics failures and of calorimeter energy deposits not associated with physics objects. The fake lepton background is found to be negligible in both CR3 and CR4.

The TFs between CR3, CR4, and the signal regions are given in Table V. Similar TFs are also computed for each channel between CR3, CR4 and the multijet control region CR2, where $W + \text{jets}$ and $t\bar{t}$ events can contribute significantly.

F. Estimated transfer factors

The transfer factors estimated using the methods described above are summarized in Table V for each CR. These values, and those between the various CRs, together with the observed event counts in each SR and CR form the inputs to the likelihood fit described in Sec. XI.

X. SYSTEMATIC UNCERTAINTIES

Systematic uncertainties arise through the use of the transfer factors relating observations in the control regions...
to background expectations in the signal regions and from the modeling of the SUSY signal. For the transfer factors derived from MC simulation the primary common sources of systematic uncertainty are the JES calibration, jet energy resolution (JER), MC modeling and statistics, and the reconstruction performance in the presence of pileup. The magnitudes of the uncertainties on background estimates arising from these sources are strongly dependent upon the signal region considered. For instance, the uncertainty due to scale variation ranges from 6% in SR-C loose to 26% in SR-A tight.

The JES uncertainty has been measured from the complete 2010 data set using the techniques described in Ref. [53] and is around 4%, with a slight dependence upon $p_T$, $\eta$ and the proximity to adjacent jets. The JER uncertainty is estimated using the methods discussed in Ref. [53]. Additional contributions are added to both the JES and the JER uncertainties to take account of the effect of pileup at the relatively high luminosity delivered by the LHC in the 2011 run. Both in-time pileup arising from multiple collisions within the same bunch crossing and out-of-time pileup, which arises from the detector response to neighboring bunch crossings, are taken into account.

The dominant modeling uncertainty in the MC simulation estimate of the numbers of events in the signal and control regions arises from the impact of QCD jet radiation on $m_\text{eff}$. In order to assess this uncertainty, alternative samples were produced with reduced initial parton multiplicities (ALPGEN processes with 0–5 partons rather than 0–6 partons for W/Z + jets production, and 0–3 instead of 0–5 for top quark pair production).

PDF uncertainties are also taken into account. An envelope of cross section predictions is defined using the 68% confidence level (C.L.) ranges of the CTEQ6.6 [63] (including the $\alpha_s$ uncertainty) and MSTW2008 [64] PDF sets, together with independent variations of the factorization and renormalization scales by factors of two or one-half. The nominal cross section value is taken to be the midpoint of the envelope and the uncertainty assigned is half the full width of the envelope, closely following the PDF4LHC recommendations [65].

Additional uncertainties arising from photon and lepton reconstruction efficiency, energy scale and resolution in CR1a, CR1b, CR3 and CR4, $b$-tag/veto efficiency (CR3 and CR4) and photon acceptance and cosmic ray backgrounds (CR1a) are also considered. Other sources, including the limited number of MC simulation events as well as additional systematic uncertainties related to the response function, are included.

Systematic uncertainties on the expected SUSY signal are estimated through variation of the factorization and renormalization scales between half and twice their default values and by considering the PDF uncertainties. Uncertainties are calculated for individual production processes (e.g. $q\bar{q}$, $g\bar{g}$, etc.).

Initial state radiation (ISR) can significantly affect the signal visibility for SUSY models with small mass splittings. Systematic uncertainties arising from the treatment of ISR are studied by varying the assumed value of $\alpha_s$ and the MADGRAPH/PYTHIA6 matching parameters. The uncertainties are found to be negligible for large sparticle masses ($m > 300$ GeV) and mass splittings ($\Delta m > 300$ GeV) and to rise linearly with decreasing mass and decreasing mass splitting to $\sim 30\%$ for $\Delta m = 0$ and $m > 300$ GeV and to $\sim 40\%$ for $m = 250$ GeV and $\Delta m = 0$. Signal ISR uncertainties are assumed to be uncorrelated with the corresponding background ISR uncertainties, to ensure a conservative treatment.

XI. RESULTS, INTERPRETATION AND LIMITS

The numbers of events observed in the data and the numbers of SM events expected to enter the signal regions, determined using the simultaneous likelihood fits (see Secs. III and IX) to the SRs and CRs, are shown in Table III. The use of transfer factors between the CRs and SRs allows systematic uncertainties and nuisance parameters to be dealt with in a coherent way, preserving any correlations, as described above. The free parameters are the background components in each SR, and these are constrained by the CR event counts and the TFs, within their uncertainties. The dominant irreducible background, from $Z + \text{jets}$ events, is constrained by both CR1a and CR1b, with CR1a providing the largest statistical weight. The resulting scaled predictions for the background components are shown in Table III. Good agreement is observed between the data and the SM predictions, with no significant excesses found. The fitted predictions for the various background components agree well with the expectations from MC simulation before the fits, once theoretical uncertainties are accounted for.

Data from all the channels are used to set limits on SUSY models, taking the SR with the best expected sensitivity at each point in parameter space. A profile log-likelihood ratio test in combination with the CL$_s$ prescription [66] is used to derive 95% C.L. exclusion regions. An interpretation of the results is presented in Fig. 10(a) as a 95% C.L. exclusion region in the $(m_{\tilde{g}}, m_{\tilde{q}})$ plane for a set of simplified SUSY models with $m_{\tilde{q}_1} = 0$. In these models the gluino mass and the masses of the squarks of the first two generations are set to the values shown in the figure, up to maximum squark and gluino masses of 2 TeV. All other supersymmetric particles, including the squarks of the third generation, are decoupled. The results are also interpreted in the $\tan\beta = 10$, $A_0 = 0$, $\mu > 0$ slice of MSUGRA/CMSSM models [67] in Fig. 10(b). In these models, ISASUSY from ISAJET [68] v7.80 is used to calculate the decay tables and to guarantee consistent electroweak symmetry breaking.

In the simplified model with light neutralinos, with the assumption that the colored sparticles are directly
produced and decay directly to jets and $E_T^{miss}$, the limit on the gluino mass is approximately 860 GeV, and that on the squark mass is 1320 GeV. Squarks and gluinos with equal masses below 1410 GeV are excluded. These values are derived from the lower edge of the 1σ observed limit band, to take account of the theoretical uncertainties on the SUSY cross sections in a conservative fashion. In the MSUGRA/CMSSM case, the limit on $m_{1/2}$ reaches...
where the solid contour represents the nominal limit, and the dotted lines are obtained by varying the cross section by the theoretical decaying via an intermediate chargino to two jets, a gluino and LSP masses in figure (a). The neutralino mass is fixed at 60 GeV in figure (b), where a neutralino LSP. 95% Exclusion limits are obtained by using the signal region with the best expected sensitivity at each point. The black dashed lines show the expected limits, with the light (yellow) bands indicating the 1σ excursions due to experimental uncertainties. Observed limits are indicated by medium (maroon) curves, where the solid contour represents the nominal limit, and the dotted lines are obtained by varying the cross section by the theoretical scale and PDF uncertainties. The 95% CLs upper limit on the cross section times branching ratio (in fb) is printed for each model point.

FIG. 12 (color online). The 95% CLs exclusion limits on simplified models assuming direct production of (a) gluino pairs with decoupled squarks or (b) squark pairs with decoupled gluinos, each decaying to two jets, or one jet, respectively, and a neutralino LSP. 95% Exclusion limits are obtained by using the signal region with the best expected sensitivity at each point. The black dashed lines show the expected limits, with the light (yellow) bands indicating the 1σ excursions due to experimental uncertainties. Observed limits are indicated by medium (maroon) curves, where the solid contour represents the nominal limit, and the dotted lines are obtained by varying the cross section by the theoretical scale and PDF uncertainties. The 95% CLs upper limit on the cross section times branching ratio (in fb) is printed for each model point.

FIG. 13 (color online). Combined 95% CLs exclusion limits on simplified models assuming direct production of gluino pairs, each decaying via an intermediate chargino to two jets, a W boson and a neutralino LSP. The chargino mass is fixed halfway in between the gluino and LSP masses in figure (a). The neutralino mass is fixed at 60 GeV in figure (b), where the y axis shows the ratio of the chargino-LSP mass splitting to the gluino-LSP mass splitting. The black dashed lines show the expected limits, with the light (yellow) bands indicating the 1σ excursions due to experimental uncertainties. Observed limits are indicated by medium (maroon) curves, where the solid contour represents the nominal limit, and the dotted lines are obtained by varying the cross section by the theoretical scale and PDF uncertainties. The 95% CLs upper limit on the cross section times branching ratio (in fb) is printed for each model point.
300 GeV at high \( m_0 \) and 640 GeV for low values of \( m_0 \). The inclusion of signal selections sensitive to larger jet multiplicities has improved significantly the ATLAS reach at large \( m_0 \). When their masses are assumed to be equal, squarks and gluinos with masses below 1360 GeV are excluded.

In Figs. 11(a) and 11(b) the limits from Fig. 10(a) are displayed again, but with the LSP mass set to 195 and 395 GeV, respectively. For both values, only minor differences are seen in the limit curve, showing that the analysis retains sensitivity for a range of LSP masses. The signal region with the greatest reach is displayed at each point in the plane, showing that the tight, medium and loose selections all contribute to the final result.

In Fig. 12 limits are shown for two cases in which only pair production of (a) gluinos or (b) squarks is kinematically possible, with all other superpartners, except for the neutralino LSP, decoupled. This forces each squark or gluino to decay directly to jets and an LSP, as in the simplified MSSM scenario. Cross sections are evaluated assuming decoupled squarks or gluinos in cases (a) and (b), respectively.

Similar models with only squark or gluino-pair production are shown in Figs. 13 and 14. However, in these variants, the particle content is augmented by an additional intermediate chargino with mass between the strongly interacting sparticle and the LSP. This allows for production of additional jets or leptons and enriches the phenomenology. In the squark pair-production case, only left-handed squarks of the first and second generations are considered in order to enhance the branching ratios of decay chains incorporating an intermediate chargino. The cross sections have been reduced by 50% to take this situation properly into account. Two different parameterizations of the masses are shown. Figures 13(a) and 14(a) vary the squark/gluino mass and the LSP mass, keeping the chargino mass exactly midway between those two. In Figs. 13(b) and 14(b), the LSP mass is instead held fixed, with the ratio of the chargino-LSP mass splitting to the squark/gluino-LSP mass splitting defining the \( y \) axis. When either mass splitting is large sensitivity to the model is enhanced by kinematics.

The “compressed SUSY” models suggested in Refs. [69,70] are also considered. In these models, the basic particle content and spectrum are similar to that in the CMSSM, but the sizes of all mass splittings are controlled by a compression factor. The squark mass is set to 96% of the gluino mass. For presentation purposes, the limits are plotted against the gluino mass and the largest mass splitting, i.e. that between gluino and LSP. Exclusion plots are shown in Fig. 15 for three classes of model: one in which all sparticle content is present, a second in which all the neutralinos and charginos apart from the LSP are taken to be sufficiently heavy to decouple, and a third in which the squarks instead are decoupled.

**FIG. 14** (color online). Combined 95% CL\(_s\) exclusion limits on simplified models assuming direct production of left-handed squark-antiquark pairs, each decaying via an intermediate chargino to two jets, a W boson and a neutralino LSP. The chargino mass is fixed halfway in between the squark and LSP masses in figure (a). In figure (b) the neutralino mass is fixed at 60 GeV; the \( y \) axis shows the ratio of the chargino-LSP mass splitting to the squark-LSP mass splitting. The black dashed lines show the expected limits, with the light (yellow) bands indicating the 1\( \sigma \) excursions due to experimental uncertainties. Observed limits are indicated by medium (maroon) curves, where the solid contour represents the nominal limit, and the dotted lines are obtained by varying the cross section by the theoretical scale and PDF uncertainties. The 95% CL\(_s\) upper limit on the cross section times branching ratio (in fb) is printed for each model point.
XII. SUMMARY

This paper reports a search for supersymmetry in final states containing high-\(p_T\) jets, missing transverse momentum and no electrons with \(p_T > 20\) GeV or muons with \(p_T > 10\) GeV. Data recorded by the ATLAS experiment at the LHC at \(\sqrt{s} = 7\) TeV corresponding to an integrated luminosity of 4.7 fb\(^{-1}\) have been used. Good agreement is seen between the numbers of events observed in the signal regions and the numbers of events expected from SM sources. The exclusion limits placed on non-SM cross sections impose new constraints on scenarios with novel physics.

The results are interpreted in both a simplified model containing only squarks of the first two generations, a gluino octet and a massless neutralino, as well as in MSUGRA/CMSSM models with \(\tan\beta = 10\), \(A_0 = 0\) and \(\mu > 0\). In the simplified model, gluino and squark masses below 860 and 1320 GeV, respectively, are excluded at the 95% confidence level for squark or gluino masses below 2 TeV. When assuming their masses to be equal, squarks...
and gluinos with masses below 1410 GeV are excluded. In the MSUGRA/CMSSM case, the limit on \( m_{1/2} \) reaches 300 GeV at high \( m_0 \) and 640 GeV for low values of \( m_0 \). Squarks and gluinos with equal masses below 1360 GeV are excluded in this scenario. These results are shown to be relatively insensitive to the assumption of a light LSP, up to LSP masses of about 400 GeV. Limits are also placed in the parameter space of a SUSY model with a compressed mass spectrum.

ACKNOWLEDGMENTS

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently. We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWF and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NSERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DNSRC and Lundbeck Foundation, Denmark; EPLANET and ERC, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT, Greece; ISF, MINERVA, GIF, DIP and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNiSW, Poland; GRICES and FCT, Portugal; MERSYS (MECTS), Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MVZT, Slovenia; DST/NRF, South Africa; MICINN, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the Royal Society and Leverhulme Trust, United Kingdom; DOE and NSF, United States of America. The crucial computing support from all WLCG partners is acknowledged gratefully, in particular, from CERN and the ATLAS Tier-1 facilities at TRIUMF (Canada), NDGF (Denmark, Norway, Sweden), CC-IN2P3 (France), KIT/GridKA (Germany), INFN-CNAF (Italy), NL-T1 (Netherlands), PIC (Spain), ASGC (Taiwan), RAL (United Kingdom) and BNL (USA) and in the Tier-2 facilities worldwide.

[19] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point in the center of the detector and the z axis along the beam pipe. Cylindrical coordinates \((r, \phi)\) are used in the transverse plane, \(\phi\) being the azimuthal angle around the beam pipe. The pseudorapidity \(\eta\) is defined in terms of the polar angle \(\theta\) by \(\eta = -\ln \tan(\theta/2)\). The transverse momentum \(p_T\) is defined in terms of the magnitude of the three momentum \(|p|\) by \(p_T = |p| \sin \theta\).
The electromagnetic energy scale is the basic calorimeter signal scale for the ATLAS calorimeters. It has been established using test-beam measurements for electrons and muons to give the correct response for the energy deposited in electromagnetic showers, while it does not correct for the lower response of the calorimeter to hadrons.

For jets, the amount of transverse energy ($E_T$) lost in the dead region can be estimated from the energy depositions in the neighboring calorimeter cells. If this lost $E_T$ projected along the $P_T^{\text{miss}}$ direction amounts to more than 10 GeV and constitutes more than 10% of the $E_T^{\text{miss}}$, the event is rejected.

137 Department of Physics, University of Washington, Seattle, Washington, USA
138 Department of Physics and Astronomy, University of Sheffield, Sheffield, United Kingdom
139 Department of Physics, Shinshu University, Nagano, Japan
140 Fachbereich Physik, Universität Siegen, Siegen, Germany
141 Department of Physics, Simon Fraser University, Burnaby, British Columbia, Canada
142 SLAC National Accelerator Laboratory, Stanford, California, USA
143a Faculty of Mathematics, Physics and Informatics, Comenius University, Bratislava, Slovak Republic
143b Department of Subnuclear Physics, Institute of Experimental Physics of the Slovak Academy of Sciences, Kosice, Slovak Republic
144 Department of Physics, University of Johannesburg, Johannesburg, South Africa

012008-32
Also at Institut für Experimentalphysik, Universität Hamburg, Hamburg, Germany.
Also at Manhattan College, New York, NY, USA.
Also at School of Physics, Shandong University, Shandong, China.
Also at CPPM, Aix-Marseille Université and CNRS/IN2P3, Marseille, France.
Also at School of Physics and Engineering, Sun Yat-sen University, Guangzhou, China.
Also at Academia Sinica Grid Computing, Institute of Physics, Academia Sinica, Taipei, Taiwan.
Also at Dipartimento di Fisica, Università La Sapienza, Roma, Italy.
Also at DSM/IRFU (Institut de Recherches sur les Lois Fondamentales de l’Univers), CEA Saclay (Commissariat a l’Energie Atomique), Gif-sur-Yvette, France.
Also at Section de Physique, Université de Genève, Geneva, Switzerland.
Also at Departamento de Física, Universidade de Minho, Braga, Portugal.
Also at Department of Physics and Astronomy, University of South Carolina, Columbia, SC, USA.
Also at Institute for Particle and Nuclear Physics, Wigner Research Centre for Physics, Budapest, Hungary.
Also at California Institute of Technology, Pasadena, CA, USA.
Also at Institute of Physics, Jagiellonian University, Krakow, Poland.
Also at LAL, Université Paris-Sud and CNRS/IN2P3, Orsay, France.
Also at Nevis Laboratory, Columbia University, Irvington, NY, USA.
Also at Department of Physics and Astronomy, University of Sheffield, Sheffield, United Kingdom.
Also at Department of Physics, Oxford University, Oxford, United Kingdom.
Also at Institute of Physics, Academia Sinica, Taipei, Taiwan.
Also at Department of Physics, The University of Michigan, Ann Arbor, MI, USA.
Also at Discipline of Physics, University of KwaZulu-Natal, Durban, South Africa.
