Ventricular preexcitation, a feature of Wolff-Parkinson-White syndrome, is caused by accessory myocardial pathways that bypass the annulus fibrosus. This condition increases the risk of atrioventricular tachycardia and, in the presence of atrial fibrillation, sudden death. The developmental mechanisms underlying accessory pathway formation are poorly understood but are thought to primarily involve malformation of the annulus fibrosus. Before birth, slowly conducting atrioventricular myocardium causes a functional atrioventricular activation delay in the absence of the annulus fibrosus. This myocardium remains present after birth, suggesting that the disturbed development of the atrioventricular canal myocardium may mediate the formation of rapidly conducting accessory pathways. Here we show that myocardium-specific inactivation of T-box 2 (Tbx2), a transcription factor essential for atrioventricular canal patterning, leads to the formation of fast-conducting accessory pathways, malformation of the annulus fibrosus, and ventricular preexcitation in mice. The accessory pathways ectopically express proteins required for fast conduction (connexin-40 [Cx40], Cx43, and sodium channel, voltage-gated, type V, α [Scn5a]). Additional inactivation of Cx30.2, a subunit for gap junctions with low conductance expressed in the atrioventricular canal and unaffected by the loss of Tbx2, did not affect the functionality of the accessory pathways. Our results suggest that malformation of the annulus fibrosus and preexcitation arise from the disturbed development of the atrioventricular myocardium.

Introduction

In the heart, the atrial and ventricular muscle masses are electrically insulated from each other by the annulus fibrosus. Normally, the only muscular connection that crosses this insulation is formed by the atrioventricular (AV) node and AV bundle. In the general population, 1–3 in 1,000 individuals have accessory myocardial pathways that bypass the insulation, known as bundles of Kent (1, 2). These accessory connections may lead to preexcitation of the ventricle, circus movement tachycardia, and even life-threatening ventricular fibrillation in the presence of atrial fibrillation, as seen in Wolff-Parkinson-White syndrome patients (3–5). The mechanism by which these accessory myocardial connections develop and the molecular properties of these connections are largely unknown.

Accessory myocardial connections that can lead to preexcitation are commonly thought to result from malformation of the annulus fibrosus (6–9). However, during development, the AV canal myocardium causes an adequate AV delay to allow synchronized alternating contraction of the atria and ventricles (10) in the absence of an annulus fibrosus. Remnant strands of this AV myocardium, which disappear when the annulus fibrosus is fully formed (6, 11), have still been observed in normal hearts around birth and after birth. Usually, these strands do not lead to preexcitation, indicating they maintain slow conduction properties of the AV myocardium. Furthermore, in the adult heart, after formation of the annulus fibrosus has been completed, slow-conducting AV

Figure 1
In the left side of the AV canal of Tbx2''- fetuses, working myocardial genes are ectopically expressed and connect the left atrium with the left ventricle, while the AV node and AV bundle are unaffected. (A, C, and D) In situ hybridization analyses of serial sections wild-type and Tbx2''- fetuses at E17.5. (A) In wild-type fetuses, the left AV canal myocardium (arrowheads) does not express Cx40 and Cx43. Tbx2''- fetuses ectopically expressed Cx40 and Cx43 in the left AV canal (arrowheads). Furthermore, the AV canal in Tbx2''- fetuses was broader. (B) 3D reconstructions of the heart of wild-type and Tbx2''- fetuses at E17.5. Green represents Cx40-positive myocardium, and gray represents Cx40-negative myocardium. Only, in Tbx2''- fetuses, a Cx40-positive myocardial connection formed through the left AV canal (red circles). (C) In the top panels, cTnl reveals the myocardium. The bottom panels show the AV node based on Hcn4 expression and location. The AV node is not affected in Tbx2''- fetuses. (D) In the top panels, cTnl reveals the myocardium. The bottom panels show the AV bundle based on Cx40 expression and location. The AV bundle is not affected in Tbx2''- fetuses. Ia, left atrium; ra, right atrium; avb, AV bundle; avn, AV node; cs, coronary sinus; lsh, left sinus horn. Original magnification, x10 (A); x5 (C and D).

heterozygous intercross matings were present at lower numbers than would be expected on the basis of Mendelian inheritance (Supplemental Figure 1C; supplemental material available online with this article; doi:10.1172/JCI44350DS1). Fetal death of Tbx2''- fetuses was less severe than that found previously for another Tbx2-null allele on the mixed C57BL/6/129/ICR background (17). Surviving E14.5 and E17.5 fetuses were of normal size and were used for further analysis. We assessed whether chamber-specific genes involved in conduction of the electrical impulse were ectopically expressed in the AV canal of Tbx2''- fetuses. In wild-type fetuses, connexin-40 (Cx40) and Cx43 were not expressed in the AV canal myocardium at E14.5 and E17.5. In contrast, Cx40 and Cx43 were ectopically expressed in the left side of the AV canal myocardium in all Tbx2''- littermates (n = 18; Figure 1A and Supplemental Figure 1A). The right AV canal myocardium was not affected in mutants (Supplemental Figure 1B). The right side of the AV canal is presumably under control of Tbx3 to a larger extent compared with the left side (18). The redundant function of Tbx3 is illustrated by the ectopic expression of Cx40 in the epicardial side of the left AV canal, complementary to that of Tbx3 at the endocardial side (Supplemental Figure 1A). Sodium channel, voltage-gated, type V, α (Scn5a), encoding the major cardiac sodium channel (Nav1.5) that is required for fast conduction, was expressed in the AV junction of Tbx2''- but not in wild-type animals. Heterozygous Tbx2 mutants were not different from wild-type animals (data not shown).
Figure 2

In the left side of AV canal of Tbx2⁻/⁻ fetuses, working myocardial proteins are ectopically expressed. The proliferation rate in the epicardium is not different between wild-type and Tbx2⁻/⁻ fetuses. (A) Immunohistochemical analyses of serial section of E14.5 wild-type fetuses and 2 Tbx2⁻/⁻ fetuses (f1, f2). In wild-type fetuses, Cx30.2 is expressed in the AV canal complementary to expression of Cx40. In Tbx2⁻/⁻ fetuses, Cx40 is expressed ectopically in the AV canal, and Cx30.2 is still expressed in the AV canal myocardium. Notice the variable size and morphology of the aberrant myocardial connection. The white and yellow arrowheads point to the AV canal myocardium. The dashed lines mark the myocardium that connects the left atrium and the left ventricle. (B) Schematic representation of the expression profiles of connexins in the left AV canal myocardium in wild-type and Tbx2⁻/⁻ fetuses. Note that Cx40 expression withdraws from the compact myocardium; however, Cx43 remains present. Dots represent nonmyocardial cells of the malformed annulus fibrosus. (C) Immunohistochemical analyses of BrdU incorporation in epicardial cells at the left side of the AV canal in a wild-type and Tbx2⁻/⁻ fetus. The panels on the right are higher magnification images of the areas within the white squares in the panels on the left. The white arrowhead points to the AV myocardium. The red arrowhead points to BrdU⁺ myocardial cells in the AV myocardium. The yellow arrowhead points to a BrdU⁺ epicardial cell. (D) A bar graph representing the proliferation rate, based on BrdU incorporation in the myocardium (myocard) of the left ventricle and in the epicardium (epicard) at the right and left side of the AV canal. RAVC, right AV canal; LAVC, left AV canal; Atr, atrium; LV, left ventricle; Sm, sulcus mesenchyme; LAVC, left AV canal; RAVC, right AV canal. Original magnification, ×10 (A and C).

In the Tbx2⁻/⁻ fetus, the compact AV node (hyperpolarization-activated cyclic nucleotide-gated channel 4 \([\text{Hcn4}]\) positive) and AV bundle (Cx40 positive) were not affected (Figure 1, C and D) and were not in contact with the aberrantly formed Cx40-positive (and Cx43-positive) myocardial connection. 3D reconstructions of E17.5 wild-type and Tbx2⁻/⁻ fetuses (Figure 1B) show the Cx40-positive pathway in the Tbx2⁻/⁻ fetus that is not connected to the AV conduction axis (Figure 1B).

To assess whether the patterns of Tbx2 and Cx40 are conserved in humans, we analyzed the expression of these proteins in a human fetus at Carnegie stage 14 (comparable to mouse E11.5). As in mice, TBX2 and TBX3 were expressed in the AV canal myocardium, whereas Cx40 was strictly absent from the AV canal myocardium but expressed in the atrial and ventricular myocardium (Supplemental Figure 2).

Next, we investigated the formation of the annulus fibrosus in Tbx2⁻/⁻ embryos. In wild-type embryos at E14.5, when annulus...
fibrosus formation is in progress, a narrow myocardial AV junction connected the atria with the ventricles. At E17.5, the atria and ventricles were almost completely separated by the annulus fibrosus, although many small myocardial connections were still observed. However, in Tbx2/− animals at E17.5, a myocardial connection in the left AV junction was formed. The size and morphology of the connection varied between animals (Figure 2, A and B). Nonmyocardial cells intermingled with the persisting myocardial connection but did not form a complete separation. The right AV junction developed normally.

In Tbx2/− animals, the sulcus mesenchyme is normally formed at the right side of the AV canal, while it is not formed at the left side. The proliferation rate of the epicardial sulcus was found to be similar between wild-type (0.36 ± 0.019 fraction of epicardial cells positive for BrdU) and Tbx2/− animals (0.38 ± 0.036 fraction of epicardial cells positive for BrdU) (Figure 2, C and D). Previously, we established an increased proliferation rate in the left AV canal of Tbx2/− animals at E9.5 (18). At E11.5, the epicardial side of the left AV canal myocardium of the Tbx2/− animals had an increased proliferation profile compared with that of the wild-type animals (Figure 2C). Neither wild-type (n = 3) nor Tbx2/− embryos (n = 3) showed apoptosis in the right AV junction myocardium and epicardium at E11.5 (data not shown). These data suggest that the annulus fibrosus is malformed due to altered migration or dysmorphogenesis of the sulcus mesenchyme.

Preexcitation of the ventricles and retrograde activation of the atria in Tbx2/− mice. In all E14.5 wild-type (n = 5) and Tbx2/− fetuses (n = 6), the left ventricle was activated from apex to base within 2 ms, after an AV delay of 67 ± 18 ms during sinus rhythm. However, we observed a functional accessory pathway in 6 out of 14 Tbx2/− fetuses. Five out of fourteen Tbx2/− fetuses showed retrograde activation of the atria after a normal AV delay. In 1 out of 14 Tbx2/− fetuses, we observed that the ventricular myocardium was completely activated via the accessory pathway during sinus rhythm, after an AV delay of only 8 ms (Figure 3 and Supplemental Videos 1–3). The location of the earliest ventricular activation coincided with the location of the accessory pathway, as shown in the 3D reconstruction (Figure 1B). The ventricular activation pattern and total excitation time of the atria and ventricles (Figure 3) indicated that the AV conduction axis (AV node and bundle) was not involved in activation of the ventricular myocardium in this heart. Nevertheless, the AV conduction axis appeared to be intact, because this heart also showed periods of normal AV conduction in which the ventricular myocardium was activated from the apex to base, with an AV delay of 51 ms.

At E17.5, the average AV conduction delay in wild-type (n = 5) and heterozygous (n = 6) mice was not significantly different (72 ± 1.3 ms and 56.1 ± 4.7 ms, respectively). In 6 out of 13 of the Tbx2/− fetuses, we found a functional, conducting accessory pathway (Table 1). One of these fetuses showed complete activation of the ventricle via the accessory pathway during sinus rhythm, with an AV delay of 8.5 ms, and 5 fetuses showed normal activation of the ventricles with subsequently retrograde activation of the left atrium. During ventricular stimulation, the ventricle to atrium conduction delay was 16.5 ± 5.5 ms in Tbx2/− fetuses and 92 ± 48 ms in wild-type fetuses (P < 0.05). We tested whether delaying AV nodal conduction would reveal concealed pathways. However, administration of adenosine did not result in AV block, suggesting absence of functional accessory pathway (n = 3).

The AV canal–specific gene program, including Cx30.2 expression, is not affected in Tbx2/− fetuses. Although all the Tbx2/− fetuses examined formed left-sided AV connections expressing working myocardial genes and had a malformed annulus fibrosus, only a subpopulation of the Tbx2/− fetuses showed a conducting accessory pathway. A possible explanation for the discrepancy is that intrinsic factors in the myocardium that are independent of Tbx2 influence conduction in the AV junction. Cx30.2 is a connexin subunit with low conductance, which is expressed in the AV node where it decelerates conduction (28), and depends on Gata factors and Tbx5 for its expression in the AV canal (24). Coimmunostaining for Cx40 and Cx30.2 revealed that Cx30.2 was expressed in the AV canal myocardium of the fetal heart complementary to Cx40 (Figure 2A). In Tbx2/− hearts, Cx30.2 remained expressed in the AV junction that now ectopically coexpresses Cx40. Expression of AV canal–specific genes, Hcm4, calcium channel, voltage-dependent, α2δ subunit 2 (Cacna2d2), calcium channel, voltage-dependent, T type, α1G subunit (Cacna1g) (Cav3.1), and inhibitor of DNA binding 2 (Idd2), was also maintained in the malformed left AV canal of Tbx2/− fetuses (Figure 4). Our findings indicate that regulation of these AV canal genes, including Cx30.2, is independent of Tbx2.
To test whether maintained Cx30.2 expression contributed to the AV delay in mutants, we generated double mutants for Tbx2 and Cx30.2 by intercrossing Tbx2<sup>fl/fl</sup> and Cx30.2<sup>tg/gt</sup> transgenic mice. AV conduction time and activation pattern were assessed by optical mapping of fetal hearts at E14.5 (<em>n</em> = 11). The fraction of Tbx2 mutants with functional bundles was not affected by the presence or absence of Cx30.2 (Table 1).

</table>

Myocardium-specific inactivation of Tbx2 results in accessory pathways and defective annulus fibrosus formation. Tbx2 is expressed in the AV canal myocardium and in the AV cushion mesenchyme, which is implicated in annulus fibrosus formation (29). Furthermore, Tbx2 is expressed in the neural crest, which has been associated with the formation of the conduction system (30), in the second heart field, and in the dorsal mesenchymal protrusion-derived cells that contribute to the AV septation process (31). We assessed the function of Tbx2 in these different cell lineages by inactivating Tbx2, specifically in endocardium and derived cushion mesenchyme, the neural crest, or the second heart field and dorsal mesenchymal protrusion-derived cells by crossing Tbx2<sup>fl/fl</sup> mice with the Tie2-Cre<sup>−/−</sup>, Wnt1-Cre<sup>−/−</sup>, and Mef2c-AHF-Cre-Tbx2<sup>fl/fl</sup> mice. Tbx2-Cre recombines all endothelia, endocardium, and derived mesenchyme of the AV cushions (32, 33). However, lineage analyses revealed that the annulus fibrosus did not receive the contributions of these cells (ref. 32 and data not shown). Wnt1-Cre labels all the neural crest, including the innervations of the heart (30). Wnt1-Cre-derived cellular contributions to the AV canal region are very limited (30, 32). In all 3 lines examined, the AV canal myocardium was normally patterned, and the sulcus mesenchyme, the precursor of the annulus fibrosus, was normally formed (Supplemental Figure 3). Tie2-Cre-Tbx2<sup>fl/fl</sup> and Mef2c-AHF-Cre-Tbx2<sup>fl/fl</sup> mice were viable, and AV conduction was not altered in adult mice (data not shown). Wnt1-Cre-Tbx2<sup>fl/fl</sup> mice died at birth due to cleft palate and were measured at E17.5. Also, in these mutants, AV conduction was not altered (data not shown).

Next, Tbx2 was specifically inactivated in the myocardium by crossing Tbx2<sup>fl/fl</sup> mice with Myh6-Cre-Tbx2<sup>fl/fl</sup> mice. At E10.5, Tbx2 protein was not found in the AV canal myocardium of Myh6-Cre-Tbx2<sup>fl/fl</sup> mutants but was still observed in the AV cushions (Supplemental Figure 4A). The left AV junction ectopically expressed Cx40, whereas Tbx3 was still expressed robustly at the luminal side of the left AV canal (Supplemental Figure 4A). The cardiac phenotype of Myh6-Cre-Tbx2<sup>fl/fl</sup> mice and Tbx2<sup>−/−</sup> mice is similar. To study annulus fibrosus formation, we assessed the patterning of the epicardial cells in the Myh6-Cre-Tbx2<sup>fl/fl</sup> mice at E12.5 by examining markers that are expressed in the epicardial cells and in the epicardial derived sulcus mesenchyme, which include periostrin (Posn), collagen, type III, a 1 (Col3al), Tbx18, and Wilms tumor 1 homolog (Wt1). In E12.5 wild-type hearts, annulus fibrosus formation was ongoing. In the AV sulcus, epicardial-derived mesenchymal cells were found that express Posn, Col3al, and Wt1. In Myh6-Cre-Tbx2<sup>fl/fl</sup> fetuses, the sulcus...
Absence of Tbx2 in the AV canal myocardium leads to absence of epicardial derived mesenchyme and abnormal epicardial patterning. (A) In situ hybridization analyses of E12.5 Tbx2'''' and Myh6-CreTbx2'''' embryos. When Tbx2 is inactivated within the myocardium Cx40 is ectopically expressed in the shortened and broadened AV canal myocardium. Furthermore, the accumulation of epicardial derived mesenchyme in the left AV sulcus is lost (black arrowheads). Dashed lines depict the contours of the myocardium (cTnl-n) and epicardial sulcus (cTnl-) in the AV region. (B) Tbx2 in the AV canal myocardium is required for correct patterning of the epicardium and the accumulation of epicardial derived mesenchyme in the AV sulcus. In situ hybridization analyses of E12.5 Tbx2'''' and Myh6-CreTbx2'''' embryos is shown. In Tbx2'''' embryos, the epicardial derived mesenchyme accumulates specifically in the AV sulcus and invaginates in between the atria and ventricles. Col3a1 (Coll3), Tbx18, and Wt1 axe expressed in the epicardium and epicardial derived mesenchyme that also expressed Postn (Pstn). In the Myh6-CreTbx2'''' embryos, the epicardial derived mesenchyme fails to accumulate in the AV sulcus, and the examined genes are aberrantly expressed (red arrowheads). Original magnification, x10 (A and B).

Mesenchyme at the left AV junction was not formed (Figure 5A). Furthermore, Col3a1 and Wt1 expression was decreased in the AV sulcus and Tbx18 expression appeared diminished (Figure 5B). This indicates that Tbx2 function in the AV myocardium influences the formation of AV sulcus mesenchyme and that the formation of the annulus fibrosus is not properly initiated. Myh6-CreTbx2'''''''' animals survived after birth at lower frequency than expected on the basis of Mendelian inheritance (P < 0.05, Table 1). This could be due to variations in the degree of recombination of Tbx2 or in viability. However, recombination by Myh6-Cre in the AV canal is complete by E10.5 (32), and a fraction of the Tbx2'''' mice also survived until late fetal stages, suggesting that the survival of the Myh6-CreTbx2'''''''' animals can be attributed to variability in phenotype. All adult Myh6-CreTbx2'''''''' animals studied (n = 7) had persisting myocardial strands that connected the left atrium with the left ventricle and that expressed Cx40 and Cx43 (Figure 6J). The myocardial connections varied in size from small strands to a relatively thick connection. More importantly, the accessory connection were always found at the left and caudal side of the AV junction and did not affect the compact AV node nor AV bundle (Figure 6, A–G). In both wild-type and Myh6-CreTbx2'''''''' mice, Cx30.2 expression was no longer detectable in the AV junction but was detectable in the AV node (Supplemental Figure 4B).

ECG recordings revealed that 4 out of 8 mice with myocardium-specific inactivation of Tbx2 had a normal PR interval (34.6 ± 4.0 ms) (Table 2). The other 4 mice showed a severely shortened PR interval, with a broadened QRS complex and initial slurring consistent with preexcitation (Figure 6H). The total activation time of the atria and ventricles with preexcitation is less than the normal AV delay. Therefore, the AV node and AV bundle complex are not used to activate (part of) the ventricle.
Hence, these QRS complexes are not a representation of a fusion of normal activation and preexcitation via the accessory bundle. We therefore prefer not to describe this initial deflection as a delta wave.

Optical mapping of adult Myh6-CreTbx2fl/fl hearts in a Langendorff setup showed that the ventricular myocardium was completely activated during preexcitation, without the involvement of the AV nodal conduction axis (Figure 6). Furthermore, all Myh6-CreTbx2fl/fl adult hearts that were investigated showed a shorter AV delay than that in wild-type hearts (13 ± 2 ms vs. 52.4 ± 8.9 ms). In some hearts, atrial echo beats could be induced after premature stimulation (Supplemental Figure 5). Arrhythmias could not be induced in any of the adult Myh6-CreTbx2fl/fl mice. Administration of sodium channel blocker ajmaline converted ventricular preexcitation into normal AV conduction (n = 3).

**Discussion**

In this study we show that global and myocardium-specific inactivation of Tbx2 causes formation of accessory AV bundles and preexcitation of the ventricles. The importance of our findings is that erroneous patterning in part of the embryonic AV canal myocardium can be the primary event in the formation of accessory pathways, leading to preexcitation and to malformation of the insulating annulus fibrosus.

The cardiac Tbx2 mutant provides a paradigm for the developmental mechanisms that can lead to accessory pathways. Both Tbx2 mutant mice and patients with preexcitation have myocardial accessory pathways that express Cx43 (34). Therefore, we propose that the formation of a fast-conducting muscular connection between the atrium and the ventricle that bypasses the AV conduction axis in the Tbx2 mutants and in patients with preexcitation can share a similar underlying developmental mechanism. However, the phenotypic outcome of these pathways differs between mice and human.

First, there is an essential difference between preexcitation in patients and preexcitation in mouse models. In contrast to patients with preexcitation, in which a delta wave is often seen, mouse models with preexcitation show activation patterns that indicate complete activation of the ventricle without involvement of the AV conduction system (35–40). In mice the AV delay is relatively long compared with the total activation time of the ventricles. Therefore, a fusion complex, as seen in humans, is less likely to occur, especially when conduction via an accessory pathway is fast. Indeed, in our model, the sum of the activation delay in the accessory pathway and the total ventricular activation time was shorter than the normal AV delay. These data indicate that in mice the ventricle is completely activated through the accessory pathways.

Second, in mice the AV node has a relatively long refractory period compared with the conduction time along the reentrant circuit. Therefore, it is difficult to induce AV nodal reentrant tachycardia in mice. However, we were able to induce an atrial echo beat via administration of a sodium channel blocker (Ajmaline) (Supplemental Figure 5).

Third, the pathways in Tbx2 mutants were variable in size and always located at the left-posterior (caudal) side of the AV junction. In patients with preexcitation, the pathways are often relatively smaller and can be located at any position in the AV junction, although there is a preference for the left and posterior location as well (41). In addition, the accessory bundles in humans are at the epicardial side of the annulus fibrosus.

Taken together, although the physiological outcome differs between patients with preexcitation and Tbx2 mutant mice, we conclude that the underlying developmental mechanisms of accessory pathway formation are similar, making the Tbx2 mutant model a valuable tool to study and understand these molecular mechanisms of accessory bundle formation.

Although an accessory connection was formed in all Tbx2 mutant fetuses that expressed Cx40, Cx43, and Scn5a, not all Tbx2 mutant fetuses had a conducting accessory pathway (Table 1). We hypothesized that other AV-specific genes may have modulated accessory pathway formation. However, the presence or absence of Cx30.2 did not influence the percentage of mutant fetuses with functional accessory pathways (Table 1). Alternatively, the size and fiber direction of the accessory bundle may vary between mutants. This can affect conduction through these accessory pathway through a mechanism known as current-to-load mismatch, in which small myocardial strands are not able to activate a large myocardial area (42). Indeed, upon blocking the sodium current, we enhanced the intrinsic current-to-load mismatch and were able to convert preexcitation into retrograde atrial activation or even normal AV conduction in the adult Myh6-CreTbx2fl/fl mice. This indicates that variations in the occurrence of current-to-load mismatch determine whether an accessory pathway causes preexcitation or not.

**Developmental mechanisms of AV accessory pathway formation.** Several mechanisms for accessory pathway formation have been put forward and discussed previously (43): (a) malformation of the annulus fibrosis (6–9), (b) acquired during fetal or postnatal life (29), and (c) misregulation of AV canal myocardium. Our study supports the latter explanation for the formation of functional accessory pathways.

During development, the AV canal provides an adequate AV delay to allow synchronized alternating contraction of the atria and ventricles (10). Remnant strands of this myocardium have still been observed in normal hearts around and after birth (11). Furthermore, in the adult heart, after formation of the annulus fibrosus has been completed, slow-conducting AV canal–type myocardium remains present around the orifices of the mitral and tricuspid valve (12–14). Defects in the annulus fibrosus alone may therefore not automatically lead to preexcitation. Our study helps to reconcile these observations. Myocardium-specific inactivation of Tbx2 caused erroneous gene expression and morphogenesis of part of the embryonic AV canal. As a result, AV myocardium was malformed and acquired fast-conducting properties, and annulus fibrosus formation was affected, which led to preexcitation. The myocardial pathways were seen to develop mainly at the epicardial side, whereas the medial/endoocardial side was largely unaffected, likely due to the redundant function of Tbx3, a functional homolog of Tbx2 (Supplemental Figure 1A) (18).

The malformation of the annulus fibrosus can be caused by disturbed epicardial ingression (29) at the level of the AV sulcus, due to dysmorphogenesis of the AV canal myocardium in Tbx2 mutants. On the other hand, the epicardium-derived mesenchymal material, which is formed before ingression, was not formed at the left side in myocardium-specific Tbx2 mutants. Furthermore, the patterning of the epicardium was disrupted, as shown by altered expression of marker genes. These findings indicate the existence of a Tbx2-dependent signal in the AV canal myocardium that is involved in the formation of the annulus fibrosus.

**Disruption of the AV canal regulatory network underlies accessory bundle formation.** Our study indicates that disturbed AV canal development is linked with formation of accessory pathways and preexcitation. Several genes have been implicated in AV
Myocardial specific deletion of Tbx2 leads to formation of accessory pathways that express Cx43 and causes ventricular preexcitation without involvement of the AV conduction axis. (A–D) Images of sections, stained via the classical Masson-trichome protocol, of a representative adult Myh6-CreTbx2<sup>2<sup>emin</sup></sup> animal. The location of each section is shown in the schematic representation in E. (E) The affected area is always located at the left and caudal side of the AV junction, while the AV conduction axis remains intact. F and G show higher magnification images of the areas within the black squares in C and D, respectively. (H) The ECG shows ventricular preexcitation in a Myh6-CreTbx2<sup>2<sup>emin</sup></sup> mouse and normal AV delay in a wild-type mouse (top). Note that the AV delay in the wild-type mouse is longer than the total activation time in the Myh6-CreTbx2<sup>2<sup>emin</sup></sup> mouse. (I) Reconstructed activation pattern of a representative wild-type mouse (top) and Myh6-CreTbx2<sup>2<sup>emin</sup></sup> adult mouse. In the wild-type mouse, after an AV delay of 34 ms, the ventricle is activated from apex to base. In the Myh6-CreTbx2<sup>2<sup>emin</sup></sup> mouse, the ventricle is activated from base to apex after an AV delay of 9 ms. (J) Immunohistochemical analyses of serial sections in Tbx2<sup>emin</sup> and Myh6-CreTbx2<sup>emin</sup> hearts. In Myh6-CreTbx2<sup>emin</sup> hearts, Cx43 is expressed in the accessory myocardial connection. vs, ventricular septum; avr, AV ring; ine, inferior nodal extension. Original magnification, x2.5 (A–D); x5 (F and G); x1 (I); x5 (J).

canal development. Bmp2-mediated signaling, essential for AV canal specification, can be detected as early as E8 in the precursors of the AV canal (15, 44). Here, it activates Tbx2, which subsequently, in concert with Tbx3 and Msx2, suppresses chamber-specific gene expression and proliferation (16–18, 21, 45). Notch activity and Hey1/Hey2 (also known as Hesr1/Hesr2) in the adjacent developing chamber myocardium restrict the Bmp2/Tbx2 pathway to the developing AV canal (19, 20). Other components that have been implicated in AV canal (AV node) development include Nkx2.5, Tbx20, Tbx5, Gata4, and Foxn4 (23–27, 46, 47). We propose that genetic or epigenetic mechanisms and environmental factors that affect these and other components of the regulatory network for AV canal development may cause dysmorphogenesis of the AV canal myocardium, acquisition of fast-conducting properties, and malfunction of the annulus fibrosus (Figure 7).

Consistently, microdeletions of BMP2 and Notch ligand, JAGGED1, have been associated with ventricular preexitation as part of a syndrome of congenital defects (48, 49). Furthermore, deletion of the Alk3 receptor (Bmpr1a, activated by, among others, Bmp2) in the AV canal myocardium in mice results in accessory pathways and AV nodal defects (7, 38).

Mutations in LAMP2 (50, 51) and PRKAG2 (35, 52) are linked to the formation of accessory pathways. In these glycogen storage diseases, it has been proposed that glycogen toxicity causes annulus fibrosus thinning that underlies formation of accessory pathways (35, 52). However, in a cardiomyocyte-specific overexpression model of mutated PRKAG, accessory pathways only developed when the mutated PRKAG was overexpressed during development. When overexpression started in adulthood, glycogen storage disease and conduction system degeneration occurred but accessory pathways did not develop, suggesting that PRKAG may play a role in AV canal development (36, 37). Nevertheless, there is not an apparent link between PRKAG and the AV canal regulatory network.

Methods

**Transgenic mice**

The Tbx2^m/m/Tie2-Cre (also known as Tbx2^m/m and Tbx2-), Tbx2^m/m, Myh6-Cre, Tie2-Cre, Wnt1-Cre, and Cx30.2^m/m alleles have been described previously (18, 28, 33, 53–55). All mice were held on the FVB/N background, except for Cx30.2^m/m mice, which were held on the C57BL/6 background. Experiments with Tbx2^m/m/Cx30.2^m/m double transgenic mice were performed in mixed FVB/N;C57BL/6 background. Animal experiments were performed in agreement with national and institutional guidelines and have been approved by the local Animal Experiments Committee, Academic Medical Center.

**Human embryos**

Human embryos were collected from medically induced abortions performed for various reasons at the Gynaecology Department of the Tartu University Hospital, Tartu, Estonia. Collection and use of the human embryonic material for research presented here were approved by the Medical Ethics Committees of the University of Tartu and the University of Amsterdam. Subsequent processing has been described previously (56).

**BrdU assay**

Pregnant female mice were injected intraperitoneally with 50 mg BrdU/kg body weight (B5002, Sigma-Aldrich) dissolved in 0.9% NaCl. After 1 hour of BrdU exposure, the mice were killed by cervical dislocation. The embryos were isolated on ice-cold PBS and further processed for immunohistochemistry.

**Immunohistochemistry and in situ hybridization**

Embryos were fixed in 4% formaldehyde, embedded in paraffin, and sectioned at 7–8 μm for immunohistochemistry and 10–14 μm for in situ hybridization. In situ hybridization was performed according to a previously described method (57). Probes have been described previously (18, 58–60). Rehydration, unmasking, blocking, and washing steps were performed, and hybridization performed using standard techniques.

**Figure 7**

Model of the transcriptional regulatory network in the AV canal myocardium that depends on Tbx2 for correct patterning of the AV canal myocardium, formation of the annulus fibrosus, and generation of AV delay.
performed according to the protocol of the tetramethylrhodamine-based amplification kit (PerkinElmer). Primary antibodies used for mouse sections were as follows: cardiac troponin I (cTnl) rabbit polyclonal (1:250; Hytest Ltd.); Tbx3 goat polyclonal (1:500; Santa Cruz Biotechnology Inc.); Cx40 mouse monoclonal (1:250; US Biological); Cx43 mouse monoclonal (1:250; BD Transduction Laboratories); Scn5a rabbit polyclonal (1:250; Alemele Labs); Nkx2.5 goat polyclonal (1:250; Santa Cruz Biotechnology Inc.); Hcn4 goat polyclonal (1:250; Santa Cruz Biotechnology Inc.); BrdU rat polyclonal (1:600; AbD Serotec), and Cx30.2 rabbit polyclonal (1:200; gift from Klaus Willecke, Institut fuer Genetik, Rheinische Friedrichs-Universitat, Bonn, Germany). For apoptosis detection, we used the Cleaved Caspase-3 antibody (rabbit polyclonal, 1:250; Cell Signaling Technology). Primary antibodies used for human sections were as follows: Tbx2 mouse monoclonal (1:100; gift from Colin Godin, Ludwig Institute for Cancer Research, Oxford University, Oxford, United Kingdom), Tbx3 goat polyclonal (1:250; Santa Cruz Biotechnology Inc.), and Cx40 rabbit polyclonal (1:250; Santa Cruz Biotechnology Inc.). Secondary antibodies when using amplification were as follows: Biotinylated donkey anti-goat (1:250; Jackson ImmunoResearch Inc.), biotinylated goat anti-rabbit (1:250, DAKO), and biotinylated goat anti-mouse (1:250; DAKO). For visualization without the amplification step, secondary antibodies coupled to an Alexa Fluor fluorescent (1:250; Invitrogen) were used.

3D reconstruction

Image acquisition, processing, and subsequent 3D reconstruction was performed according to a previously described method (61). Serial sections were stained for cTnl (labeling all cardiomyocytes) and Cx40 and reconstructed.

Preparation of the hearts and recording of electrogroms and optical action potentials

Adult hearts. ECGs were recorded for a period of 5 minutes during 1.5% isoflurane anesthesia. Signals were averaged, after which RR, PQ, QRS, QT, and QTc were calculated.

For the local recordings, mice were anesthetized by an intraperitoneal injection of pentobarbital, after which the heart was excised, cannulated, mounted on a Langendorff perfusion setup, and perfused at 37°C with Tyrode's solution (128 mmol/l NaCl, 4.7 mmol/l KCl, 1.45 mmol/l CaCl2, 0.6 mmol/l MgCl2, 27 mmol/l NaHCO3, 0.4 mmol/l NaH2PO4, and 11 mmol/l glucose [pH maintained at 7.4 by equilibration with a mixture of 95% O2 and 5% CO2]).

After that, the hearts were incubated in 10 ml Tyrode's solution containing 15 μM Di-4-ANEPPS and subsequently placed in a optical mapping setup. Excitation light was provided by a 5-watt power LED (filtered 510 ± 20 nm). Fluorescence (filtered >610 nm) was transmitted through a tandem lens system on CMOS sensor (100 × 100 elements; MICAM Ultima). Activation patterns were measured during sinus rhythm and ventricular and atrial pacing at a basic cycle length of 120 ms (twice the diastolic stimulation threshold). The effective refractory period of the AV node was determined by atrial pacing and reducing the coupling interval of a premature stimulus (after trains of 10 stimuli at basic cycle length of 120 ms) in steps of 5 ms until activation of the ventricle failed. Optical action potentials were analyzed with custom software.

Fetal hearts. Hearts were removed from the embryos and incubated for 5 minutes with Tyrode's solution containing 5 μM Di-4-ANEPPS at 37°C. After incubation, fetal hearts were superfused with Tyrode's solution and placed on the stage of a custom-made inverted microscope setup for recording optical signals.

Statistics

Group comparisons were performed using ANOVA. Values are given as mean ± SEM. Genotype and phenotype frequencies were tested with a χ2 test. A P value of 0.05 was considered statistically significant.

Acknowledgments

We thank K. Willecke, University of Bonn, for providing the Cx30.2 and T.2.2 mice and Brian Black, University of California, San Francisco, for providing the Mef2c-AHF-Cre mice. This work was supported by grants from the Netherlands Heart Foundation (2010B205 and 2008B062 to V.M. Christoffels and R. Coronel) and the European Community's Sixth Framework Programme contract (“HeartRepair” LSHM-CT-2005-018630 to V.M. Christoffels and A.F.M. Moorman).

Received for publication July 14, 2010, and accepted in revised form November 1, 2010.
