Abstract

Currently there are no evidence-based ecological measures for prevention of overgrowth and subsequent infection by fungi in the oral cavity. The aim of this study was to increase our knowledge on fungal–bacterial ecological interactions. Salivary Candida abundance of 82 Dutch adults aged 58–80 years was established relative to the bacterial load by quantitative PCR analysis of the Internal Transcribed (ITS) region (Candida) and 16S rDNA gene (bacteria). The salivary microbiome was assessed using barcoded pyrosequencing of the bacterial hypervariable regions V5–V7 of 16S rDNA. Sequencing data was preprocessed by denoising and chimera removal, clustered in Operational Taxonomic Units (OTUs) and assigned to taxonomy. Both OTU-based (PCA, diversity statistics) and phylogeny-based analyses (UniFrac, PCoA) were performed. Saliva of Dutch older adults contained 0–4 × 10³ CFU/mL Candida with a median Candida load of 0.06%. With increased Candida load the diversity of the salivary microbiome decreased significantly (p < 0.001). Increase in the Candida load correlated positively with class Bacilli, and negatively with class Fusobacteria, Flavobacteria, and Bacteroidia. Microbiomes with high Candida load were less diverse and had a distinct microbial composition towards dominance by saccharolytic and acidogenic bacteria - streptococci. The control of the acidification of the oral environment may be a potential preventive measure for Candida outgrowth that should be evaluated in longitudinal clinical intervention trials.

Introduction

In the next decades healthcare services are faced with an aging population. In the European Union the proportion of 65 year and older is predicted to reach 53% of the total population by the year 2025 [1]. An aging population forms a health risk group due to e.g. mucosal fragility) and senescence of functions (e.g., diabetes and malignancies), polypharmacies and malnutrition [2]. The internal and external factors, which contribute to changes during aging, may also disturb the balance in the oral microbial ecosystem. A disturbance in the oral homeostasis between bacteria and fungi (e.g., Candida) may cause oral infectious disease.

Candida species are a part of the commensal oral microbiota of healthy individuals at all ages with a reported prevalence between 15–75% [3,4] up to 80% in elderly, especially denture wearers [5,6]. The use of antibiotics and corticosteroids, chemotherapy, malnutrition, premature birth and old age are among the most common predisposing factors for opportunistic fungal infections i.e. mycoses [7]. The incidence of invasive fungal infections is on the rise. A study of the epidemiology of sepsis in the U.S. found that the annual number of cases of sepsis caused by fungal organisms increased by 207% between 1979 and 2000 [8]. Among the nosocomial bloodstream infections recorded in the U.S. between 1995 and 2002, 9.5% were fungal in origin with Candida spp. being the fourth leading cause of all cases [9]. Furthermore, the burden of invasive mycosis is shifting from the intensive care unit to the general hospital and even outpatient setting, where most types of mycosis represent endogenous infection in which the normally commensal host microbe take advantage of the “opportunity” to cause infection [7].

Recent advances in research on bacterial–fungal inter-kingdom communication have shown that bacteria are capable of interfering with or supporting the surrounding fungal community and vice versa [10,11,12]. It is expected that novel therapeutics will be based on “jamming” quorum sensing among pathogens and supporting communication between beneficial microbes. For practical reasons these studies are focusing on bacterial-fungal interactions in vitro at oversimplified conditions and with only a few species involved. No efforts so far have been made to assess the ecology and commensal relation of Candida with the oral microbiota at the breadth of the oral microbiome. There is an acute need to enhance our

knowledge on the ecology of fungal – bacterial interactions in search for potential targets for a guided ecological balance towards a healthy oral ecosystem.

The specific aim of this study was to assess the relationship between the load of oral Candida and the diversity and composition of the oral bacterial microbiome. For this we obtained oral bacterial pyrosequencing profiles of healthy Dutch older adults with various levels of oral Candida carriage and established that there is a relationship between the oral Candida load and the bacterial microbiome.

Results

Overall Sequencing Output

Of all reads (available at SRA of NCBI as SR0050301), 90% passed the quality control, 73% passed denoising and 59% reads (305413 reads; average length 419 nt) remained after removing the reads with chimeric sequences. The 601 unique sequences clustered into 425 OTUs of which 324 OTUs contained at least 5 reads. On average, a sample contained 87 (SD 39; min 21, max 222) OTUs. In order to avoid the effect of variable sample size on the diversity analyses, a randomly picked subset of 800 reads per sample was created and used for all subsequent analyses. After random picking of the subset of 800 reads per sample, 300 OTUs remained in the dataset with an average 43 (SD 13; min 11, max 73) OTUs per sample (Dataset S1). The subsampled reads were classified into 12 phyla (Table S1), with Firmicutes dominating the dataset (57% of reads), followed by Actinobacteria (20%), Bacteroidetes (14%) and Proteobacteria (7%). The predominant genera were Streptococcus (34% of reads), Rothia (12%), Veillonella (11%), Prevotella (10.5%), Gemella (6.9%), Actinomyces (6.7%), Neisseria (4.5%), Porphyromonas (2.6%), Haemophilus (1.8%), Lactobacillus (1.2%) and Leptotrichia (1% of reads) (Dataset S2).

Individual Microbiomes by Candida Load

Saliva of Dutch older adults contained between 0 and 14.5% Candida as a proportion of Candida specific ITS gene over bacterial DNA (16S rRNA gene), with a median Candida load of 0.06% (Table S2). The exception was a single sample (LASA181) where Candida genes dominated over bacterial 16S gene at more than three orders of magnitude (ITS/16S = 1440%). The microbial profiles of these samples showed a high interindividual variation already at the bacterial class level (Figure 1). Increase in Candida load correlated positively with reads classified as Bacillales (p = 0.013; Spearman’s rho 0.274), while class Bacteroidetes (p = 0.001; Spearman’s rho −0.360), Flavobacteria (p = 0.003; Spearman’s rho −0.322) and Fusobacteria (p = 0.012; Spearman’s rho −0.275) correlated negatively with the Candida load (Figure S1). Sample LASA181 differed in the microbial composition from the rest of the samples by dominance of genus Lactobacillus (81% of reads) and Streptococcus (16% of reads). This particular sample was the abovementioned outlier also regarding the Candida load.

Diversity statistics showed that the Candida load correlated positively with the Dominance Index (p<0.001; Spearman’s rho 0.388) and negatively with the Shannon Diversity Index (p<0.001; Spearman’s rho −0.403) (Figure 2) and the number of OTUs per sample (p=0.003; Spearman’s rho −0.321). To assess the relation of the Candida load with the individual microbiome, the samples were divided into three categories - low (<0.01% Candida), medium (0.01–0.1%) and high Candida load (>0.1%) groups. The samples with a high Candida load were less diverse than samples with low Candida (p<0.005) (Figure S2C).

The multidimensionality of the data was first reduced by an OTU-based method – Principal Component Analysis (PCA). There was no clear separation into sample clusters by the Candida load. Rather than that, a continuous gradient from low to high Candida load samples was observed (Figure 3A, arrow). Next, we applied the phylogeny-based method UniFrac to the data. UniFrac accounts for the phylogenetic divergence between the OTUs. No separation of samples was obtained in principal coordinate analysis (PCoA) on unweighted (qualitative) UniFrac distances (Figure S3A), while weighted (quantitative) UniFrac distances (Figure S3B) showed a gradient from low to high Candida load samples similar to the PCA plot.

Based on the loadings of the PCA, the OTUs that contributed most towards the low Candida load sample direction in the PC1 were classified as Prevotella (4 OTUs), Actinomyces, Veillonella, Megaplesphaera, Leptotrichia (2 OTUs) and in the PC2- Porphyromonas, Neisseria, Haemophilus and Prevotella. The OTUs that contributed towards high Candida load sample direction were classified as Streptococcus (2 OTUs), Lactobacillus (2 OTUs), Rothia and Gemella. Prevalence of OTUs classified as Lactobacillus (2 OTUs) and Scardovia were associated with the high Candida load (p<0.005, G-test, NS after Bonferroni correction). Abundance of OTUs classified as candidate division TM7, Leptotrichia (2 OTUs), Prevotella (3 OTUs), Peptostreptococcaceae, Capnocytophaga and Johsonella were associated with the low Candida load (p<0.005, ANOVA, NS after Bonferroni correction).

Individual Microbiomes by the Presence of Teeth versus Full Dentures

From the information obtained by the questionnaire we could split the subjects into a dentate (N = 34) and an edentate (N = 20) group (Table S2). The edentate subjects reported regular use of full upper and lower dentures. The dentate subjects did not report wearing any prosthesis. The remaining subjects were either partially dentate and wore partial prosthesis (N = 20) or did not fill the questionnaire completely and were classified as “Not reported” (NR) (N = 8).

Diversity statistics showed that samples from dentate subjects had significantly more OTUs per sample (mean 47, SD 11) than samples from the edentate group (mean 34, SD 14) (p = 0.001, Mann-Whitney test) and had higher sample diversity (Shannon Diversity Index 2.4, SD 0.3) than subjects with full dentures (2.1, SD 0.5) (p = 0.021) (Figure S2 D–F).

Although dentate subjects showed a trend for a lower Candida load (median 0.04%, mean 0.32%, SD 0.6) than edentate subjects (median 0.16%, mean 72.6%, SD 322), there was no statistically significant difference in the Candida load between these groups (p = 0.311, Mann-Whitney test).

The three data reduction approaches - the OTU-based PCA and the PCoA of the unweighted and the weighted UniFrac distances (Figure S4) - all stratified samples into the dentate and the edentate groups. The loadings of the PCA showed that Prevotella (4 OTUs), Actinomyces, Leptotrichia and Neisseria contributed towards the dentate group, while Rothia, Lactobacillus (3 OTUs) and Streptococcus (3 OTUs) contributed to the edentate group.

Subjects with a dentition had a higher prevalence of OTUs classified as genus Porphyromonas, Peptostreptococcus, unclassified Micrococcales, Prevotella, Solobacterium, Neisseria and Abiototrop (p<0.05; G-test; NS after Bonferroni correction) and a higher abundance of OTUs belonging to genus Prevotella, Leptotrichia, Peptostreptococcus, Porphyromonas, Solobacterium, Dialister and Porphyromonas (p<0.05; ANOVA; not significant (NS) after Bonferroni correction). Edentate subjects had a higher prevalence of Lactobacillus (p<0.05; G-test; NS after Bonferroni correction) and a higher abundance of an OTU classified as Rothia (p<0.05; ANOVA; NS after Bonferroni correction)
Bacilli (streptococci and lactobacilli) and disappearance of genera decreased and the composition changed towards dominance by *Prevotella*, *Porphyromonas* abundance of OTUs classified as *Candida* samples. The low *Porphyromonas* determined the position of the low *Streptococcus* the PCA (Figure 3B). Loadings of the PCA showed that genus increased and the bacterial profiles of saliva of Dutch older adults. With load correlated positively with reads classified as Bacilli (load in the samples (Table S2). The load samples (Figure S3C). Weighted UniFrac (Figure S3D) separated low and high *Candida* load samples (pc 0.012).

The PC 1 (18% of variance) and PC 2 (13% of variance) of the OTU-based PCA positioned most of the low *Candida* load samples and some medium load samples in the upper right quadrant of the PCA distant from the high *Candida* load samples (Figure 3B). The PCoA of the unweighted UniFrac distances showed that samples with a low *Candida* load were less dispersed than medium and high *Candida* load samples (Figure S3C). Weighted UniFrac (Figure S3D) separated low and high *Candida* load samples in a similar way to the PCA (Figure 3B). Loadings of the PCA showed that genus *Streptococcus* (4 OTUs) contributed to samples from the high *Candida* load, while *Prevotella* (3 OTUs), *Leptotrichia* (2 OTUs), *Neisseria* and *Porphyromonas* determined the position of the low *Candida* load samples. The low *Candida* load was associated with higher abundance of OTUs classified as *Prevotella*, *Porphyromonas* and *Haemophilus* (p<0.05; ANOVA; NS after Bonferroni correction).

**Discussion**

In this study we assessed the relation between the *Candida* load and the bacterial profiles of saliva of Dutch older adults. With increased *Candida* load the diversity of the salivary microbiome decreased and the composition changed towards dominance by Bacilli (streptococci and lactobacilli) and disappearance of genera within class Fusobacteria and Bacteroidia. The microbiome of dentate subjects differed from that of the fully edentate, but this difference was not significantly associated with the *Candida* load.

Saliva samples of our study group showed a large variation in *Candida* load: 0–4×10^6 CFU/ml with a median *Candida* load of 0.06%. Studies on comparable population report about 0.02% *Candida* in saliva, detected by culturing [5,13,14]. All but two (97%) of our samples were *Candida*-ITS gene positive. Studies on a similar age group, though using a culturing approach, have reported around 80% *Candida* prevalence [5,6]. This difference could be due to the lower detection limit and higher selectivity of the culturing technique compared with the qPCR on Candida-specific internal transcriber spacer (ITS) region, used here.

Due to the study logistics it was not possible to collect samples from defined intraoral habitats such as plaque, tongue or denture surfaces. Although different intraoral niches select for a habitat-specific microbiome and salivary microbial profiles show higher similarity to mucosal sites than to dental surfaces [15], saliva is frequently preferred as a representative oral sample for large clinical studies [16].

Dentures, especially in edentate individuals are known to be one of the main predisposing factors for outgrowth of *Candida* frequently leading to denture stomatitis [17]. In our study population we found only a trend for higher *Candida* load in edentulous full prosthesis wearers. The lack of statistical significance could be explained by the small sample size (20 edentulous individuals) and thus lack of statistical power, as well as by good oral and general health of the study participants. It has been shown that denture stomatitis is a multifactorial disease where poorly fitting dentures, continuously worn dentures, poor oral hygiene and reduced salivary flow all increase the ability of *Candida* to colonize the dentures and contribute to the etiology of the disease [14,17].

Saliva profiles of Dutch older adults were composed of commensal bacteria commonly found in human salivary microorganisms [15,16,18]. Pathogenic species, such as enterobacteria,
Decreased bacterial diversity is associated with a disbalanced microbiome, particularly in the dentate subgroup. Decreased diversity was seen both in relation to decreased microbiome diversity, irrespective of the absence of teeth and presence of full dentures as such already were associated with a higher diversity [19].

Perturbations such as prolonged low pH episodes reduce the diversity of microbial communities due to the presence of sucrose [27]. Staphylococcus aureus, Streptococcus gordonii, Streptococcus oralis and Streptococcus anginosus are known to coaggregate with C. albicans, especially if the yeast cells are subjected to glucose starvation [26]. These streptococcal species are able to adsorb protein components from human saliva (basic, proline-rich proteins) that in turn promote C. albicans adhesion [28]. The adherence of S. gordonii is mediated through streptococcal cell surface polysaccharide receptors and polypeptide adhesins [29]. C. albicans, on the other hand, in addition to reducing the oxygen tension to levels preferred by streptococci, may provide growth stimulatory factors for the bacteria as a result of nutrient metabolism [11]. Next to streptococci, lactobacilli were associated with high C. albicans load. While most lactobacilli are considered probiotics regarding Candida control [30], Lactobacillus casei was shown to stimulate germ tube growth – an important C. albicans virulence factor [30,31]. Both, streptococci and lactobacilli are in general acidic and acid tolerant microorganisms, often associated with dental caries pathogenesis [32].

A low C. albicans load was associated with among others, genus Prevotella, Porphyromonas and Peptostreptococcus. There are no comparable clinical reports regarding any relationships of these bacteria with fungi. In vitro studies however, two putative periodontal pathogens – Prevotella nigrescens and Porphyromonas gingivalis – have been shown to exert a suppressive effect on C. albicans viability [33], while P. gingivalis and Prevotella intermedia inhibited C. albicans germ tube formation in vitro [31]. With respect to the complexity of the oral ecosystem, it is not likely that each of the taxa is interacting with C. albicans or is affected by it directly. Our finding of Peptostreptococcus together with Prevotella in low C. albicans load samples might be due to a symbiotic relationship between these two taxa. For instance, it has been shown that Peptostreptococcus anaerobius is nutritionally dependent from Prevotella bovis (two species involved in pathogenesis of bacterial vaginosis), where P. bovis provides amino acids required for the growth of P. anaerobius [34]. Most probably multiple intermediate interactions among different metabolically dependent bacterial taxa as well as environmental conditions are affected by C. albicans or are affecting the presence of Candida. The exact mechanisms should be investigated further, both in longitudinal clinical trials and in fundamental experimental research in vitro.

The current findings strongly suggest that acidification of the environment coincides with the high load of Candida and is the major ecological factor that perturbs the oral commensal microbiome leading to the shift towards an increase of acidic microbiota and reduction of natural diversity of the bacterial microbiome. The actual sequential order of the events (i.e., what comes first – Candida outgrowth followed by acidification or primary acidification of the
oral ecosystem due to other factors such as dry mouth or high carbohydrate intake which eventually may lead to increased Candida load) can only be elucidated in well-planned longitudinal studies.

Our results bring us to two potential preventive strategies. First, the pH-lowering potential as well as duration of the low pH episode after carbohydrate consumption could be diminished by enrichment of base-producing bacteria. This could be achieved by modifying a diet from a carbohydrate- to an arginine-rich protein diet that could enhance the proportion of alkali-producing microbiota. Supplementation with prebiotics such as arginine or urea [35,36] is also known to result in base production and counteracting acidification. So far clinical tests with these supplements have been focused on the inhibition of dental caries in a young and healthy population [37] and have not involved an older adult population at risk for Candida infection. Second, the finding of inverse relationship of certain taxa with the Candida load suggests a potential in search for and the use of natural, with oral health-associated probiotic strains, in fungi-bacteria warfare. These efforts will eventually bring us closer to developing strategies for prevention of microbial shifts and Candida overgrowth and to unraveling of and interfering with the interkingdom signaling processes.

Conclusions
There is a relation between oral salivary Candida load and the bacterial microbiome profile in older adults. Microbiomes with a high Candida load are less diverse and have a distinct microbial composition predominated by streptococci. The actual role of Candida as opportunistic pathogen in shaping the microbiome should be determined in further research including fungal-microbial interactions in complex microcosm models in vitro and following natural interactions in healthy and diseased populations during longitudinal clinical trials.

Materials and Methods
Subjects and Saliva Collection
Study subjects (N = 82, mean age 66 years (SD 6.6); min 58, max 80 years; 50% females) were participants of the Longitudinal Aging Study Amsterdam (LASA) [http://www.lasa-vu.nl], a prospective study on predictors and consequences of changes in autonomy and well-being in the aging population in the Netherlands. The study was approved by the ethical review board of the VU University Medical Center (Amsterdam, the Netherlands), and all participants gave written informed consent. Subjects were chosen from three culturally distinct geographical areas in the West, Northeast, and South of the Netherlands. Details on the sampling and data collection procedures have been published elsewhere [38,39]. From the 2165 participants who participated in the measurement cycle in 2005–2006, 1421 participants were selected who were , 80 years of age, lived independently, had a good cognitive status (MMSE score >23 [40]) and were alive on January 15, 2007 for a sub-study on lifestyle including oral health. All selected persons received an extensive lifestyle questionnaire in February 2007 by mail. A total of 1058 participants (response 74.5%) returned a completed questionnaire (N = 326 no response, N = 18 refused, N = 8 not able due to physical or newly developed cognitive problems, N = 11 deceased). Information on oral health and dental status, gender and age was collected. Saliva was collected by the participants in the morning before they had taken breakfast, medicine, smoked tobacco, brushed their teeth or used any mouth rinse. Exclusion criterion was the use of antibiotics within the 3 months before saliva collection. Subjects were asked to remove their dentures during collection of saliva. Unstimulated saliva was collected by drooling into a DNA-free, sterile vial for 5 minutes [17]. The tubes were sent to the laboratory, saliva was alliquoted and stored at −80°C.

Figure 3. Salivary microbiome data by Candida load. Salivary microbiome data is plotted as OTU-based Principal Component Analysis (PCA) plot by Candida load in A) all subjects (N = 82) and in B) dentate subjects only (N = 34). Samples are colored by Candida load: green - low, blue - medium and red - high Candida load. Arrow indicates the main PC direction between low and high Candida load samples.
doi:10.1371/journal.pone.0042770.g003
DNA Extraction

Salivary DNA was extracted as described previously [16]. In brief, 0.1 ml of samples was lysed in phenol in a bead beating procedure, using 0.25–0.5 mm diameter (for breaking up the yeast cells) and 0.1-mm diameter (for breaking up the bacterial cells) glass beads (Lab Services BV, the Netherlands). DNA was extracted with the AGOWA mag Mini DNA Isolation Kit (AGOWA, Berlin, Germany) and samples were stored at –20°C until further analysis.

qPCR

Real-time qPCR was used to determine the concentration (CFU/ml) of Candida and bacteria in the saliva samples. Primers specific for the Candida ITS rDNA gene (Forward: CCTGTTTGAGCGTCTTT; Reverse: TTCTCCGCTTATTGATAT) modified from [41] were used to determine the Candida concentration. Primers and probe specific for the prokaryotic 16S rDNA gene (Forward: TCCTAGGG-GAGGCGACGACT; Reverse: GGACTAACGGGTATCTAATTCCTGTGTT, Probe: 6FAM-CGATTACCGCGGCTTCGTGAC-BBQ) [42] were used to determine the bacterial concentration. Real-time qPCR was performed using a LC480-II light cycler (Roche Diagnostics, Switzerland). As internal control for PCR inhibition a qPCR on PhHV (Phocid herpesvirus type 1 gB gene) was performed in all reactions and DNA and primers were added according to Watzinger et al. (2004) [43]. Reactions were performed with 3 μl of DNA. The total reaction volume was 20 μl. Reactions contained a 2× PCR Probe Master Mix (Roche) or, in the case of ITS primers, a 2× SYBR Green PCR Master Mix (Roche). For 16S, 7.5 pmol primers and 3.8 pmol probe, for PhHV 1.8 pmol primers and 0.4 pmol probe and for ITS 24 pmol of each primer was used. The conditions for the qPCR reaction were: an activation step of 10 min at 95°C followed by 50 cycles consisting of a denaturation step at 95°C for 30 sec, an annealing step at 60°C for 30 sec and an extension step at 72°C for 30 sec. Standard curves obtained from the overnight cultures of Candida dubliniensis and Escherichia coli were used to extrapolate DNA concentrations (CFU/ml) of the Candida (ITS) and bacterial (16S) concentration (CFU/ml) in the saliva samples, respectively. The CFU numbers were validated in saliva samples spiked with six different Candida overnight cultures (Candida tropicalis, Candida albicans, Candida glabrata, Candida parapsilosis, Candida krusei and Candida kefyr) and performing both, culturing of Candida and performing Candida specific qPCR.

Amplicon Preparation and Pyrosequencing

Amplicon libraries of the small subunit ribosomal RNA gene V5–V7 hypervariable region were generated for each of the individual samples. PCR was performed using the forward primer 785F (GGATTAGATACCCBRGTAGTC) and the reverse primer 1175R (ACGTCRTCCCCDCCTTCCTGTT). The primers included the 454 Life Sciences (Branford, CT, USA) Adapter A (for forward primers) and B (for reverse primers) fused to the 5' end of the 16S rDNA bacterial primer sequence and a unique 10 nt sample identification key.

The amplification mix contained 2 units of Phu Ultra II Fusion HS DNA polymerase (Stratagene, CA, USA), 1 unit Buffer Phu Ultra II [10x], including 2.0 mM MgCl₂ (Stratagene), 240 μM dNTP (Fermentas GMBH, Germany) 0.5 μM of each primer. To each reaction 100 pg of DNA template was added. After denaturation (95°C; 2 min), 9 cycles were performed consisting of denaturation (95°C; 30 sec), annealing (53°C; 30 sec), and extension (72°C; 80 sec), followed by 23 cycles of denaturation (95°C; 30 sec), annealing (62°C; 30 sec), and extension (72°C; 80 sec). The amplicons were purified by means of the IllustraTM GFXTM PCR DNA and Gel Band Purification Kit (GE Healthcare, Eindhoven, the Netherlands). The quality and the size of the amplicons were analyzed on the Agilent 2100
Bioanalyser with the DNA 1000 Chip kit (Agilent Technologies, Santa Clara, CA, USA). The amplicon libraries were pooled in equimolar amounts and sequenced unidirectionally in the reverse direction (B-adaptor) by means of the Genome Sequencer FLX Titanium system (Roche, Basel, Switzerland).

**Sequencing Data Analysis**

The sequencing data were processed using QIIME (Quantitative Insights Into Microbial Ecology) [44] version 1.4.0. For further downstream analyses, barcodes and primer sequences were trimmed and low quality reads (reads containing ambiguous base calls, >1 error in the primer, >1 error in the barcode, >3 nt homopolymer sequence, the average quality score below 25, or a length <150 bp or >1000 bp) were removed from the analyses. Sliding window test (50 nt) of quality scores was enabled and sequences of low quality were trimmed at the beginning of the poor quality window. The reads were denoised using Denoiser version 1.3.0 [45]. The denoised reads were checked for chimeric sequences using UCHIME version 4.2.40 [46]. The results of the de novo and the reference-based approach were combined and reads marked as chimeric were removed.

The cleaned reads were clustered into Operational Taxonomic Units (OTUs) at a minimal sequence similarity of 97% using UCLUST Reference Optimal [47]. The representative sequence of each cluster was assigned a taxonomy using the Ribosomal Database Project (RDP) classifier [48]. The minimum confidence was set at 0.8. For taxonomy assignment the SILVA rRNA database [49] was trimmed to span the targeted hypervariable regions V5–V7 as described by Brandt et al. [50]. The taxonomy assigned OTUs were aligned using PyNAST [51]. For the alignment, the minimum aligned sequence length was set at 150 nt and the minimum percent identity at 75%. FastTree [52] was used to build a phylogenetic tree of the representative sequences.

To allow comparisons among different samples, a randomly subsampled dataset of 800 reads per sample (the minimum nr of reads per sample was 881) was created. Data reduction by principal component analysis (PCA) on log2 transformed OTU data and the diversity statistics (Shannon Diversity Index, Dominance Index) was performed using PAST software [53]. Shannon Diversity index takes into account the number of taxa and the diversity statistics (Shannon Diversity Index, OTUs per sample, Dominance Index and Shannon Diversity Index). Each box shows the median, quartiles, and outliers (circles). Connector connects statistically significantly different groups ($p<0.05$; Mann-Whitney test).

**Supporting Information**

**Figure S1** Relative abundance of four bacterial classes that showed correlation with *Candida* load plotted against the *Candida* load. The abundance (nr of reads/sample) of (A) Bacilli, (B) Bacteroidia, (C) Fusobacteria and (D) Flavobacteria by *Candida* load. *Candida* load was measured as the proportion of ITS gene over 16S gene abundance by qPCR. The values were normalized by log10 transformation.

**Figure S2** Diversity statistics of salivary microbiomes by *Candida* load. Diversity statistics of salivary microbiomes by *Candida* load (A–C) in saliva and by Dentition of the subjects (D–F) as boxplots of (A, D) OTUs per sample, (B, E) Dominance Index and (C, F) Shannon Diversity Index. Each box shows the median, quartiles, and outliers (circles). Connector connects statistically significantly different groups ($p<0.05$; Mann-Whitney test).

Samples are colored by *Candida* load: green - low, blue - medium and red - high *Candida* load.

**Figure S4** Salivary microbiome data plotted by dentition. Salivary microbiome data plotted by dentition of the subjects: A) PCA of OTU-based distances, B) PCoA of unweighted (qualitative) UniFrac distances and C) PCoA of weighted (quantitative) UniFrac distances. Samples are color-coded by the dentition status of the subjects: dentate (N = 34) – blue, edentate (N = 20) – red.

**Table S1** Relative abundance of reads and number of OTUs per phylum.

**Table S2** Relative and absolute abundance of *Candida* (ITS gene) in saliva samples.

**Dataset S1** OTU-table of salivary microbiome data.

**Dataset S2** Distribution of higher taxa (genus or higher taxon) in saliva samples.

**Author Contributions**

Conceived and designed the experiments: EAK MV BJFK WC EZ. Performed the experiments: EAK M. J. Buijis. Analyzed the data: EAK M.
