CHAPTER 3

Evaluation of the occupational doses of interventional radiologists

Abstract
The aim of the present study was to determine whether there is a linear relation between the doses measured above and those measured under the lead apron of the radiologists performing interventional procedures. To monitor radiation exposure the International Commission of Radiological Protection (ICRP) recommends the use of a single dosemeter under the protective apron. To determine the exposure more accurately an additional dosemeter is recommended above the protective apron. The exposure of eight radiologists was monitored with two personal dosemeters during 3 consecutive years. To measure the doses uniformly the two dosemeters were worn in a special holder attached to the lead apron. The two personal dosemeters were replaced every 4 weeks on the same day. The doses above and under the protective aprons of seven radiologists did not differ significantly. A significant lower dose above and under the protective apron was measured for one of the radiologists. During a 4-week period the average dose measured above the lead apron was 3.44 mSv (median, 3.05 mSv), while that under the 0.25-mm lead apron was 0.12 mSv (median, 0.1 mSv). The coefficients of the regression line result in the equation \( Y = 0.036X - 0.004 \), with \( Y \) as the dose under the lead apron and \( X \) as the dose above the lead apron. The statistical analysis of the data established a linear relation between the doses above and those under the lead apron \( (R^2 = 0.59) \). Before the special holder was introduced it was not possible to derive a relation between the doses above and those under the lead apron, as the doses were measured at varying places above and under the lead apron. There is no evidence that the effective dose can be estimated more accurately when an additional dosemeter is used. The present study revealed a threshold before doses under the lead apron were measured. Due to the threshold it can be concluded that the doses under the lead apron will not be underestimated easily when doses above the lead apron are used to calculate them. This is not the case when the doses above the lead apron are calculated for the doses under the lead apron.
Introduction

Like many other hospitals the Academic Medical Centre (AMC) in Amsterdam uses personal dosemeters to monitor the occupational doses from X-ray procedures to clinical staff. The occupational doses of the majority of the clinical staff do not exceed 1 mSv in a single year. However, for clinical staff involved in fluoroscopically guided interventional procedures significant doses are measured. As a consequence of the radiation exposure, the risk of fatal cancer for the radiologists performing interventional procedures increases. This stochastic risk can increase to a value of about 0.1% for radiologists performing these procedures during many years\(^1\). In recent years the number of fluoroscopically guided interventional procedures at the AMC has increased, as has the number of radiologists performing the procedures. Moreover the discipline to wear personal dosemeters has improved. As a result the number of radiologists with doses exceeding 20 mSv in a single year has increased. Whenever the dose exceeds 20 mSv in a single year a report has to be sent to the Dutch labor inspection, even when the doses are measured above the lead apron. In the report evidence has to be given that the limit for stochastic effects is not exceeded. In order to prove that the doses of 20 mSv measured above lead aprons do not exceed the stochastic dose limit, it was decided to provide additional personal dosemeters to the radiologists performing interventional procedures at the AMC. These additional personal dosemeters were meant to monitor the occupational doses under the lead apron.

When in 2004 it was decided to provide the radiologists with an additional dosemeter, the AMC had already substantial data of doses monitored on both sides of the lead apron. These data were collected at the Department of Cardiology, where additional dosemeters were introduced in 1998. Until 2004 the data collected at the Department of Cardiology established no relation between the doses measured above and those measured under the lead apron. This was thought to be caused by the fact that the two dosemeters were often transposed, that the dosemeters were not always returned at the same time and that unmistakable instruction regarding the position of the two personal dosemeters was missing. To rule out the influence of these factors on the dose measured, it was decided to develop a special holder for the two dosemeters at the time the radiologists were provided with additional dosemeters. Moreover it was decided to replace all personal dosemeters in the study on the same day by one person, to
preclude the influence of differences in measuring periods and problems with transposed dosemeters. For this department the doses measured under the lead apron were considered to be a substitute for the effective dose as recommended by the ICRP\(^2\) while the doses measured above the lead apron were used to estimate the effective dose more accurately.

The aim of the present study was to determine whether a relation exists between the doses measured above and those measured under the lead aprons of radiologists performing interventional procedures and whether two personal dosemeters provide additional information compared to a single dosemeter.

**Materials and Methods**

From 2004 onward the occupational doses of eight radiologists involved in interventional fluoroscopically guided procedures were monitored by means of two personal dosemeters. The personal dosemeters were used to measure the doses above and under the lead aprons of the radiologists. To receive consistent measurements the two dosemeters were worn in a specially designed holder that was fixed to the lead apron (Figure 1 and Figure 2). The holder with the two personal dosemeters was worn breast-high. The two dosemeters were replaced every 4 weeks on the same day, while the holder remained fixed to the lead apron during the whole study.

The doses were measured during 39 periods of 4 weeks in 3 consecutive years. At the start of the study six of the radiologists were provided with two personal dosemeters, while throughout the study another two radiologists were provided with two dosemeters. Three radiologists left the AMC before the end of the study.

The personal dosemeters were provided by the Nuclear Research and Consultant Group (NRG, Arnhem, the Netherlands). The personal dosemeters were read by the NRG and reported to the AMC. The dosemeters contain LiF:Ti, Mg (TLD100) detectors behind 2 mm of aluminum for the measurements at a depth of 10 mm. In the dose reports the doses were presented by means of the personal dose equivalent at a depth of 10 mm, the \(H_p(10)\). The doses were reported in multiples of 0.01 mSv. Doses below 0.005 mSv were reported as <0.01 mSv\(^3\).
At the Department of Radiology the interventional procedures were performed with two Philips Integris Allura machines (Philips Medical Systems, Best, the Netherlands) with the same potential range of 50-133 kVp.

During all interventional procedures the radiologists used wraparound lead aprons (skirts and vests, Scanflex Medical AB, Täby, Sweden) with an overall lead equivalence of 0.25 mm at 100 kV. The wrap around apron has an overlap due to which the actual thickness of the protective apron in the front is 0.5 mm lead equivalent. The doses were monitored above and under a layer of 0.25 mm lead equivalence.

The doses measured above and under the lead apron were statistically analyzed using SPSS-software (release 11.5.1 for Windows). Under the lead apron doses <0.01 mSv were treated as 0 mSv for the statistical analysis. Above the lead apron doses <0.01 mSv were entered as missing values. For the statistical analysis the doses under the lead apron were entered as dependant variables while the doses above the lead apron and the eight radiologists were independent variables. Statistical significant differences were set at a level of 5% (p= 0.05).
Results

During the study 392 dosemeters were provided to eight radiologists. All dosemeters were returned to the NRG. The doses were read and reported in 13 4 weekly dose reports. In total 196 doses were recorded above the lead apron, ranging from <0.01 mSv to 16.78 mSv. Under the lead apron the doses ranged from <0.01 mSv to 0.83 mSv. Five readings were excluded from the study as the doses measured above and under the lead apron were reported to be <0.01 mSv. In 27 cases the doses measured under the lead apron were <0.01 mSv. These doses were treated as 0 mSv in the statistical analysis.

In Tables 1 and 2 and in Figures 3 and 4 the mean dose, the median and the quartiles above and under the lead apron are presented for the eight radiologists. A Kolmogorov-Smirnov test showed that the doses of the eight radiologists were normally distributed (p>0.05). The doses measured above and under the lead apron differed significantly among the eight radiologists (one-way ANOVA, p<0.05). The
Levene's test established that the variance of the doses measured above and under the lead apron of seven radiologists was equal (p>0.05). The doses of these seven radiologists did not differ significantly (one-way ANOVA, p>0.05). The average dose of the seven radiologists was 3.85 mSv in 4 weeks above the lead apron and 0.13 mSv in 4 weeks under the lead apron. The average dose of radiologist 5 was 1.79 mSv in 4 weeks above the lead apron and 0.07 mSv under the lead apron. The dose above the lead apron of radiologist 5 differed significantly from the doses of radiologists 6, 7 and 8 (Tamhane post hoc analysis, p<0.05). Under the lead apron the dose of radiologist 5 differed significantly from the dose of radiologist 7 (Tamhane post hoc analysis, p<0.05).

**Table 1:** The number of measurements, mean dose, standard deviation and the percentiles (25th, 50th [median] and 75th) of the doses measured above the lead apron of the radiologists 1 to 8.

*aThese doses differ significantly (p < 0.05).*
In Figure 5 the doses measured under the lead apron are plotted against the doses above the lead apron. The statistical analysis of the data established a linear relation between the doses above and those under the lead apron (ANOVA, $p< 0.05$, $R^2 = 0.59$). The coefficients of the regression line representing the relation between the doses measured above and those under the leaded apron were derived resulting in the equation $Y = 0.036 X - 0.004$ with $Y$ as the dependant variable (dose under the lead apron) and $X$ as the predictor value (dose above the lead apron). The 95% confidence interval for the coefficients ranged from 0.034 to 0.038. The standard error of the models tested was 0.07. The standard error of the model was lower than the standard deviation of the average dose under the lead apron (0.11). The residuals were normally distributed ($p>0.05$) (Figure 6).

![Figure 3: Boxplot of the doses (mSv) measured above the leaded apron. The black line in the box marks the median, the box boundaries the 25th and 75th percentiles and the whiskers the minimum and maximum observed values that are not statistically outlying. In the plot the extreme values are marked with an asterisk. The extreme values are more than 3 box lengths from the upper edge of the box. The box length is the interquartile range.](image)
The linear relation was not influenced by the doses measured for radiologist 5. The equation remained the same. With the equation and the lowest detectable dose under the lead apron (<0.005 mSv) the corresponding dose above the lead apron was calculated: <0.25 mSv. Above this threshold the relation between doses above and those under the lead apron was determined another time. The statistical analysis once again established once more a linear relation (ANOVA, p<0.05). The coefficients of the regression line remained the same. Only the strength of the model was lower ($R^2 = 0.57$).

**Discussion**

The dose measurements above and under the lead apron established that the occupational exposure of the radiologists performing interventional procedures in the AMC is comparable. There was only one exception: radiologist 5. As radiologist 5 performed fewer procedures than his colleagues his exposure was expected to be lower. It was, however, unknown what reduction in doses was to be expected, as data on the number and the lengths of procedures were not collected for the study. Despite this, it is likely that the lower exposure of radiologist 5 was caused by a lower workload as the doses above and under the lead apron decreased proportionally compared to the other radiologists: 46% and 50%.

Results of doses measured above and under the lead apron of physicians performing interventional procedures have been published by several authors. Moreover, measurements for cardiologists performing interventional procedures were carried out. Renaud et al.\(^4\) reported about measurements above and under the lead aprons of in-room personnel during cardiac catheterization. Vano et al.\(^5\) published measurements of cardiologists during a 15-year follow-up. However, differences in the way radiologists and cardiologists perform interventional procedures make it difficult to compare the doses of cardiologists and radiologists. A limited number of clinical studies on doses above and under the lead apron have been carried out amongst radiologists. Williams et al.\(^6\) reported average monthly doses above the lead aprons of radiologists that ranged from 1.08 to 6.55 mSv. The highest average dose in this study was found for a radiologist who performed all interventional procedures in patients with liver disease. The average dose of the other radiologists in the study was 1.56 mSv. The findings of
Figure 4: Boxplot of the doses (mSv) measured under the lead apron. The black line in the box marks the median, the box boundaries the 25th and 75th percentiles and the whiskers the minimum and maximum observed values that are not statistically outlying. Extreme values are marked by an asterisk. The extreme values are more than 3 box lengths from the upper edge of the box. The box length is the interquartile range.

Figure 5: Plot of doses (mSv) measured above the lead apron (X-axis) and under the lead apron (Y-axis). The line in the plot represents the equation for the regression.
Williams et al. are comparable to the average dose above the lead apron in the present study, where the doses varied between 1.09 mSv and 3.21 mSv.

Niklason et al.\textsuperscript{7} published annual radiation doses above the lead aprons of 28 radiologists. The average annual dose in their study was 48 mSv. The average annual dose in the study by Niklason et al. was higher than the average annual dose in the present study: 45 mSv. However, the average annual dose found by Niklason et al. was lower than the average annual dose when radiologist 5 was excluded. The average annual dose of the seven remaining radiologists was 50 mSv.

In the studies by Williams et al. and Niklason et al. the doses under the lead apron were also measured. Williams et al. found that the average monthly dose under the lead apron ranged from 0 to 0.48 mSv. As for the results above the lead apron, Williams et al. reported that the highest average dose was caused by the differences in the nature of work of one of the radiologists. The average monthly dose under the lead apron of all other radiologists (the radiologist with the highest dose was excluded) was 0.08 mSv. In the present study the doses under the lead apron varied between 0.06 and 0.2 mSv in a 4-week period weeks. The average dose, 0.12 mSv, was higher than the average dose reported by Williams et al. The differences between the two studies are possibly caused by the differences in thicknesses of the lead aprons between them. Williams et al. reported that the doses were measured under lead aprons of 0.35 and 0.5 mm while in the present study doses were measured under a layer of 0.25 mm.

Niklason et al. measured doses under lead aprons of 0.25 mm and 0.5 mm. As for the doses measured above the lead apron, the doses under the lead apron were annual doses. The average annual dose under the lead apron reported by Niklason et al. was 0.88 mSv while in the present study the average annual dose was 1.6 mSv (median 1.3 mSv). As for the results reported by Williams et al., the differences in doses were probably caused by the variation in thickness of the lead aprons worn by the radiologists.

In the study reported by Williams et al., the radiologists ensured that the personal dosemeters were worn in all cases. However, the personal dosemeters under the lead aprons were worn not only worn during interventional procedures but also during other
radiology procedures. The authors described that the dedication of the radiologists to wearing additional dosemeters under the lead apron was probably less consistent than for the other dosemeters. In the present study the dedication of the radiologists was not tested as the dosemeters were simultaneously worn in the special holder. Moreover the dosemeters in this study were worn exclusively during interventional procedures.

The duration of the measurements in the study by Niklason et al. was approximately 2 months while in the present study the doses of the majority of the radiologists were measured during 3 consecutive years.

The regression analysis revealed a linear relationship between the doses measured above and those measured under the lead apron. The relation was described by the formula $Y = 0.036X - 0.004$. The slope of the line (0.036) is a measure of the transmission of the lead aprons. In the present study a transmission of 3.6% was found for lead aprons of 0.25 mm. This transmission was derived breast-high, at the height of the lead collar of radiologists. According to Kharrati et al. the energy of the scattered radiation at the height of the lead collar of radiologists is ~ 70 kVp. The transmission fraction in the present study (3.6%) is in accordance with the data on transmission factors of different primary beam energies found by other authors. Murphy et al. found a transmission factor of 3% for lead aprons of 0.3 mm in the primary beam of 80 kVp. Vano et al. found a fraction transmitted through lead aprons of 0.25 mm lead aprons of between 3.3% at 70 kVp and 5.7% at 80 kVp. Christodoulou et al. reported about transmission fraction through lead aprons of 0.25 mm at a tube potential of 70 kVp. The transmission fraction ranged from 4.3% up to 10%.

From the formula $Y = 0.036X - 0.004$ the intercept of the regression line can be calculated. The intercept with the X-axis lies at 0.11 mSv. This value theoretically represents the threshold of the doses above the lead apron before doses under the lead apron. This means that for the doses above the lead apron of < 0.11 mSv, only doses below the diction limit are expected. The doses will be reported as < 0.01 mSv. As doses up to 0.005 mSv are below the detection limit of the dosemeters and are reported as doses < 0.01 mSv, the theoretical threshold is even higher: 0.25 mSv versus 0.11 mSv for the doses above the lead apron. As a matter of fact, in the present study for all measurements above the lead apron < 0.25 mSv the corresponding doses under the
lead apron were reported to be below the detection limit of 0.01 mSv. The lowest dose in this study above the lead apron for which a dose under the lead apron of 0.01 mSv reported was 0.59 mSv.

The minimum thickness recommended by the IAEA\textsuperscript{11} for lead aprons of radiologists performing interventional procedures is 0.35 mm. In the present study the doses were measured at 0.25 mm. The doses were measured under one layer of wrap around lead aprons. Due to the overlap of these aprons the thickness of the lead apron in the front of the radiologists was 0.5 mm. For practical reasons it was decided to measure the doses under one layer of 0.25 mm despite the fact that the doses measured were higher than the occupational doses to the body of the radiologists. The occupational doses of the radiologists under the lead apron in this study are therefore overestimated.

![Distribution of the residuals (mean = 0, standard deviation = 1).](image)

**Figure 6**: Distribution of the residuals (mean = 0, standard deviation = 1).

The present study showed that additional monitoring under the lead apron is not necessary to estimate the occupational exposure more accurately. This result is in agreement with the conclusions of Schultz et al.\textsuperscript{12} who came to the conclusion based on dose calculations with Monte Carlo simulations. A transmission of 3.6\% for lead aprons $\geq 0.25$ mm does not underestimate the exposure for radiologists.
In the present study the doses under the lead apron were determined almost at the same place as the doses above the lead apron. This was possible as a special holder was used. Before the special holder was introduced it was not possible to derive a relation between the doses above and those under the lead apron.

**Conclusion**

The aim of the present study was to determine whether a relation exists between the doses measured above the lead apron and those measured under the lead apron of radiologists performing interventional procedures and whether two personal dosemeters provide additional information compared to a single dosemeter. It might be concluded that a linear relation between the measurements above and under the lead apron is proved in this study. With this, there is no evidence for a more accurate estimation of the effective dose when an additional dosemeter is used.

As the results of this study were derived from measurements by radiologists performing interventional procedures, it is not known whether a factor of 0.036 is applicable for other specialists performing interventional procedures such as interventional cardiologists and electro physiologists. For this reason, more investigation is needed to derive correction factors for other physicians performing interventional procedures.
