Abstract
The effects of pre-incubation with mercury (Hg²⁺) and cadmium (Cd²⁺) on the activities of individual glycolytic enzymes, on the flux and on internal metabolite concentrations of the upper part of glycolysis were investigated in mouse muscle extracts. In the range of metal concentrations analysed we found that only hexokinase and phosphofructokinase, the enzymes that shared the control of the flux, were inhibited by Hg²⁺ and Cd²⁺. The concentrations of the internal metabolites glucose-6-phosphate and fructose-6-phosphate did not change significantly when Hg²⁺ and Cd²⁺ were added. A mathematical model was constructed to explore the mechanisms of inhibition of Hg²⁺ and Cd²⁺ on hexokinase and phosphofructokinase. Equations derived from detailed mechanistic models for each inhibition were fitted to the experimental data. In a concentration-dependent manner these equations describe the observed inhibition of enzyme activity. Under the conditions analysed, the integral model showed that the simultaneous inhibition of hexokinase and phosphofructokinase explains the observation that the concentrations of glucose-6-phosphate and fructose-6-phosphate did not change as the heavy metals decreased the glycolytic flux.

Introduction
The concentration of heavy metals in the environment has increased significantly over recent decades [1]. Much of this is due to increased human activity such as industrial activity, traffic, smelting, fossil fuel combustion and agriculture [2]. These metals cannot be degraded and their accumulation in the food chain produces human health risks and ecological disturbances [3,4]. The toxicity of each metal depends on many factors, including the duration, quantity and exposure method, as well as the chemical form in which it exists. Once assimilated by the body, metals can cause a variety of cytotoxic reactions [5,6,7,8,9]. They may affect essential metabolic pathways in cells [7] or lead to the production of reactive oxygen species (ROS), which affect various cellular processes, including the functioning of the membrane system [10]. Many studies have reported the biological implications of metal toxicity in metabolic and associated physiological processes [11,12,13,14], including the effect of cadmium, mercury and copper on the upper part of glycolysis or on the process of tubulin polymerization [15,16,17]. The mechanisms of toxicity of these heavy metals include the interaction with proteins due to the high affinity of the former for the free electron pairs in cysteine SH groups [7,10,18,19]. These groups can determine the structure and conformation of the enzyme or engage in catalysis at the active centre of the enzyme.

Metabolic control analysis (MCA) has been used extensively to quantify enzyme control on system variables, usually steady-state fluxes and metabolite concentrations [20,21,22,23,24]. This control is evaluated by means of control coefficients, which are sensitivity coefficients of these system variables in terms of activity changes of one enzyme, e.g. $C_E = \frac{d \ln (\text{flux})}{d \ln (\text{enzyme activity})}$. In previous works, we observed that, in extracts of mouse skeletal muscle, hexokinase (HK) and phosphofructokinase (PFK) shared control of the metabolic flux in the upper part of glycolysis [15,25]. Also, we characterized the irreversible inhibitory effects of pre-incubation with copper and we identified HK...
and PFK as the main targets of copper [15]. This led us to propose that other heavy metals affect metabolic functions through their irreversible effects on HK and PFK. The main aim of this study is to test this hypothesis by identifying the flux control mechanism and sites of action of two other heavy metals, Hg^{2+} and Cd^{2+}, in the upper part of glycolysis. We therefore pre-incubated mouse muscle extracts with these toxic agents and then characterized the effect of increasing the concentrations of both on activities of individual enzymes, flux of the overall multi-enzymatic pathway, intermediate metabolite concentrations and flux control coefficients.

Materials and Methods

Chemicals

ATP (sodium salt), NADP^+, NADH, glucose (Glc), glucose-6-phosphate (G6P), fructose-6-phosphate (F6P), fructose-1,6-bisphosphate (FBP), HK, aldolase (ALD), triose-phosphate isomerase (TPI), glucose-6-phosphate dehydrogenase (G6PDH), α-glycerol-3-phosphate dehydrogenase (GDH), PFK, phosphocreatine (PC), creatine kinase (CK), Cd(NO₃)₂, Hg(NO₃)₂, HEPES and 3-(N-morpholino)propanesulfonic acid (MOPS) were purchased from Panreac (Spain). NADH = 0.75 mM, MgATP = 2 mM, MgCl₂ = 20 mM, PC = 3 U/ml CK, 3.5 U/ml TPI and 0.5 U/ml GDH. NADH consumption was monitored at 385 nm (ε⁰⁰ nm = 75 mM⁻¹ cm⁻¹), as described by Puigjaner et al. [25], using a Shimadzu UV-2101PC Spectrophotometer with 1-cm light path cells. These assay conditions are not quite representative for muscle muscle in vivo, but in view of the considerable amount of consensus building required to achieve proper in vivo standard conditions [27], we here reverted to conditions that are not far off from the in vivo state and that our previous work [15,25] has shown to work well.

Extracts were pre-incubated with Cd(NO₃)₂ (0.7 μM) and Hg(NO₃)₂ (0.1 μM) in standard buffer at 37 °C for 60 min. The reaction was then started by adding 100 μl of the reaction mixture to 900 μl of the pre-incubated extract.

Determination of the metabolite concentrations

The metabolite concentrations were determined when, in the above assay, the NADH consumption proceeded at a constant rate. The reaction was stopped at different intervals by adding ice-cold HClO₄ to a final concentration of 10% and neutralized to pH 7.0 with KOH/MOPS (6M/0.6M). After 10 min, the precipitate was removed by centrifugation for 10 min at 14000 x g. The supernatants were used for the enzymatic determination of G6P and F6P, in accordance with Bergmeyer [28].

Modulation of steady-state flux and metabolite concentration by external enzymes and determination of flux control coefficients

The steady-state flux was measured when commercial enzyme (HK) or partially purified enzyme (PFK) was added to the extract in order to determine the control coefficients using classical titration analysis. In each case the appropriate amounts of enzyme were added to the extract pre-incubated with Cd(NO₃)₂ or Hg(NO₃)₂ in a standard buffer for 60 min at 37 °C. The reaction was started with the addition of 100 μl of the reaction mixture containing the appropriate amounts of commercial enzyme or partially purified enzyme to 900 μl of the pre-incubated extract. Since a large quantity of exogenous enzyme was added, it was not necessary to determine the enzymatic activity with accuracy. Flux control coefficients were estimated using the Small and Kacser method for large changes in enzyme activity [29], for the conversion of Glic to triose-phosphates (TrP).

Measurements of activities of individual enzymes

The maximal catalytic activities of HK, glucose-6-phosphate isomerase (GPI), PFK and ALD were measured under substrate enzymes TPI and GDH. The final concentrations in the cuvette were 2 mM NADH, 2 mM MgATP, 10 mM Glc, 20 mM PC, 3 U/ml CK, 3.5 U/ml TPI and 0.5 U/ml GDH. NADH consumption was monitored at 385 nm (ε⁰⁰ nm = 75 mM⁻¹ cm⁻¹), as described by Puigjaner et al. [25], using a Shimadzu UV-2101PC Spectrophotometer with 1-cm light path cells. These assay conditions are not quite representative for muscle muscle in vivo, but in view of the considerable amount of consensus building required to achieve proper in vivo standard conditions [27], we here reverted to conditions that are not far off from the in vivo state and that our previous work [15,25] has shown to work well.

saturation in the standard buffer with 900 μl of pre-incubated extract mixture (the pre-incubated extract mixture contained Cd(NO₃)₂ (0–7 μM) or Hg(NO₃)₂ (0–10 μM) and, for flux control coefficient determinations, the appropriate amounts of commercial or partially purified enzymes) at 37 °C. GPI and ALD individual activities were measured in accordance with Bergmeyer’s methods.

**Figure 2. HK and PFK activities.** Effect of increasing pre-incubating concentrations of Cd²⁺ (A,B) or Hg²⁺ (C,D) on individual HK activity (A,C) and PFK activity (B,D). The length of the error bar on either side of the mean values represents one standard deviation (SD). Thus, all values are mean ± 1 SD. Solid lines represent the fitting of the activities of HK (A and C) or PFK (B and D) to the respective equations (A and B for equation (2), C and D for equation (1)).

Effects of Cadmium and Mercury on Glycolysis

Inhibition of glycolytic enzymes by Hg$^{2+}$ and Cd$^{2+}$

In order to establish the experimental conditions, we first examined the time dependence of the inhibition of HK, GPI, PFK and ALD by Hg$^{2+}$ and Cd$^{2+}$. Mouse muscle extracts were pre-incubated with different Hg$^{2+}$ concentrations (0–7 μM) for up to 1 h at 37°C. After the incubation time, the activities of individual enzymes were measured. In the range of Hg$^{2+}$ and Cd$^{2+}$ concentrations tested, HK activity and PFK activity decreased with pre-incubation time until they reached a limit value after 1 h. The GPI activity and ALD activity remained constant during this time interval for all Hg$^{2+}$ and Cd$^{2+}$ concentrations tested. In the following experiments, pre-incubation times of 1 h were used.

In the control samples without heavy metals, the decrease in activities of individual enzymes was around 5%. HK activity was inhibited by Cd$^{2+}$ and Hg$^{2+}$ in a concentration-dependent manner (Fig. 2A and Fig. 2C, respectively). The IC$_{50}$ were estimated as the concentration of Cd$^{2+}$ or Hg$^{2+}$ for half activity. The IC$_{50}$ for HK were around 5 μM for Cd$^{2+}$ or Hg$^{2+}$. Cd$^{2+}$ and Hg$^{2+}$ also inhibited PFK activity, virtually to the same extent and at the same concentrations as they inhibited HK (Fig. 2B and Fig. 2D). In this case, the IC$_{50}$ was around 3 μM for Cd$^{2+}$ and 6 μM for Hg$^{2+}$.

Effects of Hg$^{2+}$ and Cd$^{2+}$ on the steady-state flux of triose phosphate production and on steady-state intermediate metabolite concentrations

The results of the effects of Cd$^{2+}$ and Hg$^{2+}$ on the steady-state flux of TrP production and the steady state of G6P and F6P concentrations are shown in Fig. 3. The IC$_{50}$ for the steady-state flux of TrP production from G6P was around 5 μM for Cd$^{2+}$ and around 3.5 μM for Hg$^{2+}$. These values are close to the corresponding IC$_{50}$ values for HK and PFK, which would suggest that these enzymes had a high level of control over the measured flux. The distribution of the control of the flux of TrP production can be estimated by flux control coefficients [23]. These control coefficients were determined experimentally (for additional details see Materials & Methods). In the absence or presence of the heavy metals ([Cd$^{2+}$] = 5 μM, or [Hg$^{2+}$] = 3.5 μM), the resulting flux control coefficients for HK ($C_{HK}$) and PFK ($C_{PFK}$) were in the range 0.91–0.96 and 0.11–0.25, respectively. The distribution of control among the enzymes was not significantly changed by the toxic agents, nor were the steady-state G6P and F6P concentrations when the extract was pre-incubated with different concentrations of Cd$^{2+}$ or Hg$^{2+}$ (Fig. 3).

Mathematical model of irreversible inhibition

The measured decreases in activities of individual enzymes resulting from inhibition by Hg$^{2+}$ and Cd$^{2+}$ were embedded in a mathematical model. A model describing the concentrations and flux through the upper part of glycolysis as a function of rate laws of the individual enzymes in mouse muscle extracts had previously been developed [25]. As described in Fig. 1, HK follows a simple Michaelis-Menten kinetics equation and PFK a Hill equation in this model. The limiting rates ($V$) for HK, GPI, PFK and ALD are such that the flux control coefficients for HK and PFK were 0.85 and 0.15, respectively, which are within the observed ranges.

With respect to the irreversible inhibition by Hg$^{2+}$ or Cd$^{2+}$ on HK activity and PFK activity, we proposed the mechanistic models depicted in Fig. 4. For Hg$^{2+}$, a first mechanistic model takes into account that Hg$^{2+}$ only affects $V$ and not the $K_{M}$ or $K_{S}$. The equations derived from scheme in Fig. 4A for HK and PFK inhibition by Hg$^{2+}$ are presented in detail in Appendix S1. The resulting $V$ dependency on metal concentrations is detailed in the following equation:

$$V = V^0(1 - K_4[Hg^{2+}])$$

(1)
where $V_0$ refers to the limiting rate in the absence of $\text{Hg}^{2+}$ and $K_A$ is the apparent inactivation constant. The model predicts that the inactivation is linearly related to the added concentration of $\text{Hg}^{2+}$. This is confirmed by Fig. 2C and 2D: a straight line fits the experimental results, which led us to estimate that the $K_A$ was 92 mM$^{-1}$ for HK and 76 mM$^{-1}$ for PFK.

The obtained experimental data on the irreversible inhibition exerted by $\text{Cd}^{2+}$ on HK activity and PFK activity (Fig. 2A and 2B) cannot be fitted using the model in Fig. 4A, which considers a 1:1 stoichiometry for the binding between the metal and the enzyme. For this case, we considered an alternative mechanistic model (see Fig. 4B and Appendix S1). $\text{Cd}^{2+}$ binds to m+1 sites, and only when this bind is complete, inactivation takes place. This leads to the following expression for the $V$ dependence on the concentration of the added inhibitor:

$$V = V_0(1 - K_A [\text{Cd}^{2+}])^{m+1}$$  \hspace{1cm} (2)

where $m$ is 1 for HK and 2 for PFK, $V_0$ refers to the limiting rate in the absence of $\text{Cd}^{2+}$ and $K_A$ is the apparent inactivation constant of $\text{Cd}^{2+}$. Fig. 2A and 2B show the mathematical fitting for $\text{Cd}^{2+}$ for both enzymes, leading us to estimate that the $K_A$ was 0.017 $\mu$M$^{-1}$ for HK and 0.0029 $\mu$M$^{-1}$ for PFK.

The substitution, in the mathematical model described in Fig. 1, of the $V$ of HK ($V_{\text{HK}}$) and PFK ($V_{\text{PFK}}$) by the new $\text{Cd}^{2+}$ or $\text{Hg}^{2+}$ dependent expressions (equation (1) and equation (2)) reproduced the observed behaviour approximately, as shown in Fig. 3. This figure provides a direct comparison of the experimental data for maintenance of the metabolite concentrations and decrease of the flux, respectively, with the model predictions.

### Structural analysis of metal inhibition

Irreversible inhibition of enzymes by metals is usually attributed to the binding to amino acid residues (Cys and His being the most common) that are essential for enzyme activity or stability. To analyse the feasibility of metal inhibition from a structural point of view, 3D model structures of HK and PFK were examined to determine possible target residues for metal binding. Comparative models were obtained from ModBase (see Materials and Methods section) and inspected. Table 1 shows a summary of the results obtained. Candidate Cys residues were selected taking into account the exposure of the side chain, and their distance to relevant structures such as active sites and intersubunit contacts. In both cases, the analysis showed a significant number of candidate residues. Particularly relevant examples are Cys 581 and Cys 794 on HK in the intersubunit interface (Fig. 5A) and Cys 233 on PFK located at the ATP-binding site (Fig. 5B). Binding of such residues to metal ions greatly influences either the stability of the protein, in the case of HK, or the ability to bind ATP, for PFK, leading to irreversible inactivation. There are no Cys residues near the active sites of GPI and ALD.

### Discussion

We previously analysed [25,34] the first four steps of glycolysis in muscle extract, optimized the experimental system and characterized the control role and properties of HK and PFK in the upper part of glycolysis. In a subsequent study, we identified HK and PFK as the sites of action of $\text{Cu}^{2+}$ [15]. Here we found the effects of $\text{Cd}^{2+}$ and $\text{Hg}^{2+}$ on the enzymes, flux and concentrations of the upper part of glycolysis in mouse muscle extract to be similar to our previous findings for copper. The similarity is especially strong for mercury and copper. Interestingly, the same equations [15] explain the irreversible inhibition observed experimentally, but with different parameters.

The analysis of Fig. 2 and 3 reveals that, for HK activity, PFK activity and the flux of TnP production, the relative decrease for increasing concentrations of $\text{Cd}^{2+}$ or $\text{Hg}^{2+}$ is similar. This implies similar IC$_{50}$ values for the enzymes and the flux for $\text{Cd}^{2+}$ or $\text{Hg}^{2+}$. However, the patterns of decay for increasing concentrations of $\text{Cd}^{2+}$ and $\text{Hg}^{2+}$ are different, with a more linear decay for $\text{Hg}^{2+}$. Also, the analysis of the G6P and F6P concentrations shows that

they are unchanged in both incubations with Cd\(^{2+}\) and Hg\(^{2+}\) (Fig. 3), as was also previously reported for Cu\(^{2+}\) [15]. Both metabolites are the intermediaries among the reactions catalysed by HK and PFK, which are in rapid equilibrium through the reaction catalysed by GPI.

The analysis of the control coefficients \( C_{HK} \) and \( C_{PFK} \) calculated from the experimental data were in perfect agreement with the values previously reported in our studies with mouse muscle extracts [15,25]. These were in the range 0.8–0.9 and 0.1–0.2, respectively. These data are also consistent with data reported in the literature for other cell types [35,36]. According to the flux summation theorem of MCA, the sum of all flux control coefficients is one, and all control coefficients in a linear pathway are positive:

\[
C_{HK} + C_{GPI} + C_{PFK} + C_{ALD} = 1
\]

This suggests that HK has the majority of control of the upper part of glycolysis in muscle extract and PFK has the remainder. There is no significant flux control in GPI and ALD. HK and PFK, the enzymes that share the control of the flux, are also the enzymes that are inhibited when pre-incubated with copper [15], cadmium and mercury, while GPI and ALD, which have no control, are almost unaffected by these heavy metals. The distribution of control is not changed significantly by the toxic agents, which is consistent with the observed maintenance of metabolite concentrations, since the elasticity coefficients [23], which cause the control coefficients to assume their values, are not affected by the inhibitors.

The simultaneous decrease of the limiting rates of HK and PFK, the enzymes controlling the flux, is equivalent to a minimal implementation with only two enzymes of multisite modulation, which is an efficient way by which organisms achieve very large flux changes, but with only small concentration changes in internal metabolites [37,38,39]. Fig. 6 plots the dependence of the metabolite concentrations on HK and PFK limiting rates as shades of grey. Only a close-to-proportional reduction in HK and PFK limiting rates allows the relative concentrations of the intermediate metabolites to be maintained at a constant level. Our data suggest that for Cu\(^{2+}\) [15] the inhibition mechanisms of HK and PFK follow this proportionality almost perfectly (solid line in Fig. 6A). For Cd\(^{2+}\) (solid line in Fig. 6B) and Hg\(^{2+}\) (solid line in Fig. 6C), this does not differ a great deal. The higher similarities for Cu\(^{2+}\) and Hg\(^{2+}\) are not surprising because they fit the same equations that describe the inhibition of HK and PFK. A simple explanation could be that all of these heavy metals inhibit all enzymes through the same mechanism, based on their high affinity for the free electron pairs in cysteine SH groups, which are important in enzyme function. The structural analysis of HK and

---

**Figure 6. Model predictions showing the dependence of G6P concentrations on HK and PFK limiting rates.** The proportional dysregulation predicts the broken grey line. The shades in the panels report the predicted G6P concentrations when the limiting rates of HK and PFK do not change proportionally. Solid black lines correspond to the model predictions for different levels of pre-incubation with Cu\(^{2+}\) (A), Cd\(^{2+}\) (B) and Hg\(^{2+}\) (C). They indicate how the metals change the limiting rates of the two enzymes and the consequent changes in metabolite concentrations. The same plot is for F6P, as G6P and F6P are in rapid equilibrium through the reaction catalysed by GPI.

doi:10.1371/journal.pone.0080018.g006
PFK (Table 1 and Fig. 5) revealed a significant number of candidate cysteine residues. Interestingly, the formation of organized structures could protect against these inhibitory effects, as it has been suggested for the complex association of proteins/enzymes to microtubules in neuronal systems [16,17]. Indeed a combination of iron or microtubule assembly and the flux of Glc conversion to T3P was observed in bovine brain extract, which also resulted in a decreased sensitivity to copper toxicity [16]. A subsequent analysis in bovine brain extract showed that tubulin diminished the inhibitory effect of not only copper but also cadmium and mercury on the upper part of glycolysis [17]. However, the flux-stimulating effect of microtubules in brain extract was not seen in mouse muscle extract [16].

The fact that pre-incubation with these heavy metals decreases the flux without altering the metabolite concentrations, at least in the upper part of glycolysis analysed, suggests that, at low pollutant concentration, its effects could be silent at metabolite levels, even though the glycolytic flux is affected. Depending on the turnover rate of the enzymes, the irreversible inhibition of heavy metals over the two key enzymes of glycolysis, HK and PFK, could have long-term cumulative effects. We would expect the level of the glycolytic enzymes to be controlled by the performance of the pathway, which suggests that irreversible damage to the enzymes would be repaired by the synthesis of new enzyme molecules. It is important to understand whether the heavy metal ion is detoxified within the cell or if the faulty enzyme molecules that contain the heavy metal ion are degraded. The effects on glycolytic flux of adding different heavy metals, the regulatory mechanisms of enzyme synthesis and the detoxification mechanisms should be taken into account when defining the permitted concentrations of these metals in water.
