INTRODUCTION

Plants produce green leaf volatiles (GLVs), C6-aldehydes, C6-alcohols, and their acetates, through the lipoxygenase (LOX) and hydroperoxide lyase (HPL) pathways. Linolenic and linoleic acid are the substrates for dioxygenation and subsequent cleavage to obtain C6-volatile aldehydes that can be further modified by alcohol dehydrogenases (ADH), an isomerization factor and an acetyltransferase leading to the formation of a bouquet of secondary metabolites (Bate and Rothstein, 1998; Arimura et al., 2000; Farag and Paré, 2002; Engelberth et al., 2004; Halitschke et al., 2004; Kishimoto et al., 2005, 2006; Paschold et al., 2006), resulting in the production of defensive compounds (Zeringue, 1992; Bate and Rothstein, 1998; Farag et al., 2005, 2006; Frost et al., 2007, 2008; Heil and Silva Bueno, 2007). Similarly, the E-2-hexenal released by rice upon planthopper infestation, induces expression of defense-related genes, increasing resistance to bacterial blight (Gomi et al., 2010). In some of these examples the effect of GLVs and jasmonic acid (JA) signaling have been linked (Engelberth et al., 2004; Halitschke et al., 2004; Kishimoto et al., 2006; Allmann et al., 2010; Tong et al., 2012).

Green leaf volatiles (GLVs) are C6-molecules – alcohols, aldehydes, and esters – produced by plants upon herbivory or during pathogen infection. Exposure to this blend of volatiles induces defense-related responses in neighboring undamaged plants, thus assigning a role to GLVs in regulating plant defenses. Here we compared Arabidopsis thaliana ecotype Landsberg erecta (Ler) with a hydroperoxide lyase line, hpl1, unable to synthesize GLVs, for susceptibility to Pseudomonas syringae pv. tomato (DC3000). We found that the growth of DC3000 was significantly reduced in the hpl1 mutant. This phenomenon correlated with lower jasmonic acid (JA) levels and higher salicylic acid levels in the hpl1 mutant. Furthermore, upon infection, the JA-responsive genes VSP2 and LEC were only slightly or not induced, respectively, in hpl1. This suggests that the reduced growth of DC3000 in hpl1 plants is due to the constraint of JA-dependent responses. Treatment of hpl1 plants with E-2-hexenal, one of the more reactive GLVs, prior to infection with DC3000, resulted in increased growth of DC3000 in hpl1, thus complementing this mutant. Interestingly, the growth of DC3000 also increased in Ler plants treated with E-2-hexenal. This stronger growth was not dependent on the JA-signaling component MYC2, but on ORA59, an integrator of JA and ethylene signaling pathways, and on the production of coronatine by DC3000. GLVs may have multiple effects on plant-pathogen interactions, in this case reducing resistance to Pseudomonas syringae via JA and ORA59.

Keywords: green leaf volatiles, Pseudomonas syringae, jasmonate, coronatine, hormone crosstalk
Finally, GLVs possess fungicidal and bactericidal activity (Proost et al., 2005; Shiojiri et al., 2006b). Since GLVs are released after infection with pathogenic fungi and bacteria (Croft et al., 1993; Heiden et al., 2003; Shiojiri et al., 2006b), this testifies that a possible physiological role of these volatiles is to limit pathogen growth. Several observations support this hypothesis. For instance, upon infection with the pathogenic bacteria *Pseudomonas syringae*, *Phasmosus vulgaris* (lima bean) leaves release relatively high amounts of the C6-aldehyde β-2-hexenal and the C6-alcohol Z-3-hexenol (Croft et al., 1993). Moreover, pre-treatment with the β-2-hexenal as well as genetic manipulation to enhance C6-volatile production, resulted in increased resistance against the necrotrophic fungus *Botrytis cinerea* in Arabidopsis, most likely as a result of both activation of defense responses and direct inhibition of fungal growth (Kishimoto et al., 2005; Shiojiri et al., 2006b). Since GLVs are released after infection with pathogenic fungi and bacteria (Croft et al., 1993), this suggests that a possible role of these volatiles is to limit pathogen growth. Several observations support this hypothesis. For instance, upon infection with the pathogenic bacteria *Pseudomonas syringae*, *Phasmosus vulgaris* (lima bean) leaves release relatively high amounts of the C6-aldehyde β-2-hexenal and the C6-alcohol Z-3-hexenol (Croft et al., 1993). Moreover, pre-treatment with the β-2-hexenal as well as genetic manipulation to enhance C6-volatile production, resulted in increased resistance against the necrotrophic fungus *Botrytis cinerea* in Arabidopsis, most likely as a result of both activation of defense responses and direct inhibition of fungal growth (Kishimoto et al., 2005; Shiojiri et al., 2006b). Since GLVs are released after infection with *Pseudomonas syringae* pv. *tomato* DC3000 (DC3000) causes bacterial spot on tomato (Capecchi, 1986), but also on *A. thaliana* (Whalen et al., 1991), DC3000 produces coronatine (COR), a toxin, responsible for chlorotic halos, which mimics the action of JA-isoleucine (JA-Ile), the active form of JA. With this phytoalexin DC3000 exploits the antagonistic interaction between JA and salicylic acid (SA) in order to shut down SA-dependent defenses that plant triggers to fight against *Pseudomonas* infections (Blümel et al., 2005; Glavenbook, 2005).

We especially focused on the role of β-2-hexenal during the *Arabidopsis-Pseudomonas* interaction. Although it is not the most abundant C6-volatile produced by HPL, activity, β-2-hexenal is emitted during *Pseudomonas* sp. infections in lima bean (Croft et al., 1993) and in tobacco (Heiden et al., 2003), and it has the highest bacterial activity in vitro among oxylipins (Proost et al., 2005), likely because its α,β-unsaturated carbonyl moiety that can react with nucleophilic groups (Farmer and Davoine, 2007). Additionally, β-2-hexenal has been shown to induce several responses in *Arabidopsis*, including induction of defenses, inhibition of root growth and enhancement of resistance against the necrotrophic fungus *B. cinerea* (Bate and Rothstein, 1998; Kishimoto et al., 2005; Milsbilla et al., 2008). In order to determine the role of GLVs in the responses against *Pseudomonas*, we set out to study *Arabidopsis* plants with and without a functional HPL (Shiojiri et al., 2012) and did complementation studies with β-2-hexenal. Remarkably we found that the presence of a working copy of HPL increased susceptibility of *Arabidopsis* to DC3000. Treatment with β-2-hexenal also enhanced the susceptibility to this bacterial pathogen. We found evidence that this is mediated by the transcription factor ORA59, one of the main players in the JA-signaling pathways, and required the production of the bacterial toxin COR.

### MATERIALS AND METHODS

#### PLANT LINES

*Arabidopsis thaliana* ecore-type Columbia-0 (Col-0) and Landsberg erecta (Let) were used. The hpl mutant is an introgression line between Col-0 and Ler (Shiojiri et al., 2012). The mutant myc2 (jim1-7; Verhage et al., 2011), the transgenic lines RNAi-ORAS9 and the 3SS:GUS plants (Pré et al., 2008) were all in the Col-0 background. Plants were grown in soil in a growth chamber at 21°C, 70% relative humidity under an 11-h photoperiod with 100 μE m⁻² s⁻¹.

#### BACTERIAL POPULATION COUNTS

Bacteria were grown overnight at 28°C in liquid King's broth (KB) medium (King et al., 1954) containing rifampicin (50 μg/ml) for the *Pseudomonas syringae* pv. *tomato* DC3000 strain, and kanamycin (100 μg/ml) for the cor-1 DC3682 mutant strain, unable to produce COR (Ma et al., 1991). Plants were inoculated with either a low dose (OD₆₀₀ of 0.0007), for bacterial growth assays, or a high dose (OD₆₀₀ of 0.007), for qRT-PCR and hormone quantification, of the bacterial suspension, and bacteria (colony forming units, cfu) were counted as reported in Park et al. (2010).

#### PLANT HORMONES EXTRACTION AND QUANTIFICATION

For JA and SA quantification, 12 leaves were harvested, in pools of 4, from 12 different mock-infected (10 mM MgSO₄) or bacteria-infiltrated plants in two independent experiments. To extract JA and SA, frozen leaf material (50–150 mg) was ground and homogenized in 0.5 ml 70% methanol, spiked with 200 ng of D6-JA and D6-SA (internal standards for extraction efficiency; CDN Isotopes, Canada)³, with a PicoEx24 automated lysate preparation Technologies². Samples were homogenized twice by shaking at 6,000 rpm for 40 s and centrifuged at 10,000 g for 20 min at 4°C. The supernatants of two extraction steps were pooled. JA and SA were quantified by liquid chromatography–mass spectrometry (LC–MS) analysis on Varian 320 Triple Quad LC/MS/MS. Ten microliters of each sample were injected onto a C18 Pursuit 5 (50 mm × 2.0 mm) column (Varian) coupled to a double mass spectrometer in tandem (Varian 320 MS–MS³). The mobile phase comprised solvent A (0.05% formic acid) and solvent B (0.05% formic acid in methanol) as follows: 85% solvent A for 1 min 30 s (flow rate 0.4 ml/min), followed by 3 min in which solvent B increased till 98% (0.2 ml/min) which continued for 5 min 30 s with the same flow rate, followed by 2 min 30 s with increased flow rate (0.4 ml/min), subsequently returning to 85% solvent A in 1 min, conditions that were kept till the end of the run, in total 15 min. Compounds were detected in the electrospray ionization negative mode. Molecular ions [M-H]⁻ at m/z 137 and 209 and 141 and 213 generated from endogenous SA and JA and their internal standards, respectively, were fragmented under 12 V collision energy. The ratios of ion intensities of their respective daughter ions, m/z 95 and 97 and m/z 59 and 63, were used to quantify endogenous SA and JA, respectively.

QUANTITATIVE RT-PCR
For analysis of transcript levels, total RNA was isolated using Tri-
zol from 10 infiltrated leaves, harvested from 10 different plants,
in three independent experiments and treated with Turbo DNA-
free (Ambion®) to remove DNA. CDNA was synthesized from 1 μg
of total RNA using M-MuLV reverse transcriptase (Fermentas®),
as described by the manufacturer, in a 20-μl reaction that was
diluted to 50 μl prior to using it for the real-time PCR. This was
performed in a 20-μl volume containing 2.5 μl of CDNA, 0.4 pmol
of specific primer sets for each gene and 10 μl of iQ® SYBR
Green Supermix with ROX (Bio-Rad®). PCR conditions were as
follows: 95°C for 2 min 30 s (first cycle), 95°C for 15 s and 60°C
for 30 s (40 cycles). To ensure amplification of a single product
during the qRT-PCR reactions, a dissociation protocol was per-
formed in which samples were slowly heated from 55 to 95°C.
qRT-PCR was performed using the ABI Prism 7000 real-time
PCR detection system (Applied Biosystems) and the data were
collected using software (ABI 7000 SDS version 1) provided by
the supplier. Transcript levels were normalized to the levels of the
SAND gene (At2g28390; Hong et al., 2010) and quantification was
performed as described in previous work (Pfaffl, 2001). Primer
sequences were as reported in (Anderson and Badruzzaufari, 2004;
Czechowski et al., 2005; Park et al., 2010) for PRI, VSP2, LEC, and
SAND, respectively.

TRYPAN BLUE AND ANILINE BLUE STAINING
Trypan blue staining solution was prepared by adding trypan blue
to lactophenol (10 ml lactic acid, 10 ml glycerol, 10 ml phenol,
and 10 ml distilled water) to a concentration of 2.5 mg/ml. Two
volumes of ethanol were added to the trypan blue–lactophenol
solution. To visualize plant cell death, mock and DC3000 infected
leaf tissues were placed in plates containing staining solution and
heated in a microwave at intervals for 1 min. The plates were
incubated for 2 h at room temperature, followed by destain-
ing (three times) in chloral hydrate (25 g/ml). The leaf tissues
were mounted in 70% glycerol for observations with a micro-
scope. For detection of callose deposition, leaves were incubated
for at least 24 h in 96% ethanol until all tissues were transpar-
ent and stained in 0.01% aniline blue in 0.15 M K2HPO4 (pH
8.5). Leaf tissues were incubated for 1.5–3 h, mounted on slides,
and observed under an epifluorescence microscope (AF6000) with
a Cy2 filter (excitation filter: BP 470/40 nm; emission filter: BP
525/50 nm).

CALLOSE QUANTIFICATION
Callose was quantified from digital photographs as the number of
white pixels, covering the whole leaf material, using Photoshop
CS7 software. Contrast settings of photographs were adjusted to
obtain an optimal separation of the callose signal from the back-
ground signal. Callose was selected automatically, using the "Color
Range" tool. In cases in which the contrast settings resulted in
significant loss of callose signal, due to high autofluorescence of
vasculature tissue, callose was selected manually, using the "Magic
Wand" tool of Photoshop CS7. Relative callose intensities were
quantified as the number of fluorescent callose-corresponding pix-
els relative to the total number of pixels covering plant material
(Luna et al., 2013).

E-2-HEXENAL TREATMENT
Plants were grown for 3 weeks under the conditions mentioned
above before being exposed to volatiles. For the volatile treat-
ment, 10 plants in single pots were placed into airtight glass
descicators (22 l). E-2-hexenal was diluted in methanol, and
applied to a sterile cotton swab, placed in an Erlenmeyer flask,
between the plants in the descicators to give a final concentration
of 3 μM. For the control treatment, only methanol was applied.
Plants were incubated in the descicators for 24 h and subsequently
taken out to be placed under the growth conditions described above
for 1 h, prior to infiltration with bacteria or mock solu-
tion as mentioned above. E-2-hexenal was purchased from Sigma-
Aldrich.

RESULTS
hpl1 INFLUENCES SUSCEPTIBILITY TO Pseudomonas syringae pv.
tomato (DC3000)
In order to determine whether the ability to synthesize GLVs had an
effect on Arabidopsis susceptibility to pathogenic bacteria, we
compared Landsberg erecta (Ler, L) and an introgression line
between Col-0 and Ler that can synthesize only trace amountes
of GLVs, hpl1 (Shoji et al., 2012), for the susceptibility to
Pseudomonas syringae pv. tomato DC3000. To ensure infection
throughout the entire leaf, we used the syringe infiltration method
since it overcomes stomatal defenses and maximizes the number of
responding cells (de Torres Zabala et al., 2009), and bacterial pop-
ulations were determined 72 hpi (hours post-infection). Figure 1
shows that DC3000 populations were lower in the hpl1 line. The
difference measured in bacterial population between Ler and hpl1
(∼4.6-fold) was statistically significant (t-test P < 0.05). This
indicates that the hpl1 line is less susceptible to DC3000 than Ler.
hap1 influences JA and SA levels during the infection with DC3000

It is well known that the balance between JA and SA is crucial for the interaction that will be established between a pathogen and its host (Spoel and Dong, 2008; Grant and Jones, 2009; Pieterse et al., 2009). We therefore monitored the changes in JA and SA in Ler and the hap1 plants, prior to the bacterial population measurement, at 2, 24, and 48 hpi. As shown in Figure 2A, the levels of JA were up at 2 hpi in all treatments, most likely because of the mechanical damage caused by the inoculation with the syringe. At 24 hpi, this wound response was reset, as JA levels were very low, comparable to the mock inoculation. The situation changed at 48 hpi when JA levels increased in DC3000-infested leaves, in Ler approximately threefold higher than in hap1. SA levels (Figure 2B) changed already at 24 hpi, with levels being approximately 1.7-fold higher in hap1 than in Ler, suggesting that SA-related defenses are activated earlier in hap1. In Ler, the SA levels were higher than in hap1 at 48 hpi suggesting that these defenses are mounted later in Ler.

JA marker genes are less induced in hap1 than Ler when infected with DC3000

In order to determine whether the differences in hormone levels had an effect on the expression of relevant marker genes in our system, we performed qRT-PCR for genes downstream of JA and SA. We chose VSP2 and LEC for JA (Potter et al., 1993; Penninckx et al., 1998; Thomma et al., 1998; Liu et al., 2005; Pré et al., 2008) and FR-1 for SA (Bowing et al., 1997; Clarke et al., 2001). FR-1 expression was clearly induced by DC3000 at 48 hpi, however, similar levels in Ler and hap1 plants (Figure A1 in Appendix). In contrast, transcript levels of both VSP2 and LEC at 48 hpi (and 24 hpi) were much lower in hap1 than in Ler (Figures 3A,B). This result is consistent with the observed lower JA levels in hap1 at 48 hpi (Figure 2A).

Ler (hap1) and hap1 differ in the number of dead cells and in callose deposition

To investigate further the differences between Ler and hap1 in mounting plant defense responses, we decided to look at the appearance of dead cells and callose deposition. Dead cells are indicative of programmed cell death (or the hypersensitive response, HR) and enhanced resistance, usually occurring when an pathogenic effector is recognized by the host (Alfano and Collmer, 1996), whereas callose is typically triggered by conserved pathogen-associated molecular patterns (PAMPs), such as flag-ellin, at the sites of infection during the relatively early stages of pathogen invasion (Brown et al., 1998; Gómez-Gómez et al., 1999; Jones and Dangl, 2006). Dead cells appeared earlier and more abundantly in the more susceptible hap1 (Figures 4A–C). Dead cells started to deposit callose massively at day 1, while much less papillae at this time could be observed in hap1. Moreover, even at later stages of infection, at days 2 and 3, Ler showed more callose deposition than hap1.

E-2-hexenal treatment increases susceptibility to DC3000

Since hap1 is unable to produce GLVs, we addressed the question whether application of GLVs would restore its susceptibility to DC3000 comparable to Ler. We chose to use the C6-aldehyde E-2-hexenal, one of the most active GLVs, and treated hap1 and Ler plants with 3 μM aerial E-2-hexenal or with the carrier methanol (MeOH) for the control treatment. Figure 5A shows that the treatment with the C6-aldehyde turned both hap1 and Ler more susceptible to DC3000, as bacterial populations increased about five- and ninefold, respectively, in the E-2-hexenal pre-treated

...
leaves compared to the control pre-treatment (Figure 5B). Additionally, we measured JA and SA levels in Ler and hpl1 plants infected with DC3000 after pre-treatment with E-2-hexenal or MeOH. Although JA and SA levels increased 48 hpi after DC3000 infection, no significant differences in hormone levels were detected between the E-2-hexenal and the control treatment or between Ler and hpl1 (Figure A2 in Appendix).

THE EFFECT OF E-2-HEXENAL ON BACTERIAL GROWTH ACTS VIA ORA59.

Since a functional HPL leads to higher susceptibility and higher JA levels upon DC3000 infection and E-2-hexenal pre-treatment increased susceptibility of Arabidopsis to DC3000 we sought to elucidate part of the signaling pathways involved, by testing if Arabidopsis mutants in the JA-signaling pathway were still more susceptible to DC3000 after treatment with E-2-hexenal. We chose to analyze MYC2 and ORA59 impaired lines since these are the main players in regulating JA-dependent responses and are located in two different branches of the JA-signaling pathway (Lorenzo et al., 2003, 2004; Anderson and Badruzsaufari, 2004; Dombrecht et al., 2007; Oñate-Sánchez et al., 2007; Kazan and Manners, 2008;
Hydroperoxide lyase promotes susceptibility to *Pseudomonas*

FIGURE 5 | E-2-hexenal pre-treatment increases susceptibility to DC3000. (A) DC3000 populations in Ler and hpl1 pre-treated with 3 μM E-2-hexenal or methanol were measured 72 hpi. Values are the mean of 16 sets of two leaf disks from 12 plants. Error bars represent standard error. The data presented are from a representative experiment that was repeated four times with similar results. All pre-treatments with E-2-hexenal were significantly different from the control treatment (P < 0.05, according to Student’s t-test analysis). (B) Bars represent the ratio between cfu/cm² with E-2-hexenal pre-treatment and cfu/cm² with methanol pre-treatment (control). Values are the mean of three independent experiments. Error bars represent standard error.

Pré et al., 2008). As shown in Figure 6A, *myc2* (*jin1-7*) plants were more resistant to DC3000 as has been reported (Fernández-Calvo et al., 2011). Moreover, *myc2* as well as wild-type plants showed increased susceptibility to DC3000 when pre-treated with E-2-hexenal, seemingly excluding a role for MYC2 in mediating this phenomenon. In contrast, the same assay performed on RNAi-ORA59 plants (Pré et al., 2008) showed that the bacterial populations increased significantly less in the ORA59 silenced plants compared to the corresponding control line after E-2-hexenal treatment (Figure 6B). This indicates an involvement of ORA59 in this response to E-2-hexenal.

THE E-2-HEXENAL EFFECT IS CORONATINE DEPENDENT

*Pseudomonas syringae* pv. *tomato* strain DC3000 synthesizes COR (Mitchell, 1982), a phytoxin that mimics JA-Ile (Thines et al., 2007; Yan et al., 2009), in order to antagonize the SA-dependent defenses (Brooks et al., 2000; Glazebrook, 2005). Therefore, we also determined whether the production of COR was necessary for DC3000 to proliferate more in E-2-hexenal treated plants. For this, Ler and hpl1 plants were infected with the *Pseudomonas syringae* mutant strain DC3682 (Ma et al., 1991), that is unable to produce COR, after pre-treatment with E-2-hexenal or methanol. Figure 7 shows that the bacterial populations of the cor mutant were only slightly, but significantly, higher in Ler or hpl1 plants treated with E-2-hexenal compared to the control plants, but that this increase was much lower than for DC3000 (Figure 1). Thus COR seems to be necessary for DC3000 to benefit from the E-2-hexenal treatment.

DISCUSSION

Green leaf volatiles have received considerable attention for their ability to induce direct and indirect defense responses in plants and can be considered important players in the already complex network regulated during biotic stress. However the mechanisms by which GLVs influence pathogenesis, and the signaling pathways involved in these responses, are not well known. To address this, we used Ler and its *Arabidopsis* introgression line, hpl1, lacking GLV synthesis, and analyzed their response during infection with the bacterial pathogen *Pseudomonas syringae* pv. *tomato* (DC3000). DC3000 was chosen because in some plant species such as lima bean and tobacco, infection triggers E-2-hexenal emission (Croft...
We hypothesized that hpl1 plants would be more susceptible to DC3000 since there is evidence that GLVs and E-2-hexenal have antimicrobial properties (Prost et al., 2005), induce defense-related genes or biosynthesis of defense-related secondary metabolites (Bate and Rothstein, 1998; Arimura et al., 2001; Gomi et al., 2003; Weber et al., 2004; Farag et al., 2005; Kishimoto et al., 2005, 2006; Paschold et al., 2006), and increase resistance against rice where the mutant Os hpl1 were more resistant to DC3000 (Figures 1A,B). A similar result was found the opposite result: plants impaired in GL V production that a non-functional HPL from Oryza sativa synthesize GLVs, was more resistant to P. syringae pv. coronatine. Bacterial populations of the mutant (DC3682) in inoculated Ler and hpl1 leaves at 72 hpi. Plants were pre-treated 24 h with 3 μM E-2-hexenal or methanol. Values are the mean of 24 sets of two leaf disks from 20 plants. Error bars represent standard error. All pre-treatments with E-2-hexenal were significantly different from the control treatment (p < 0.05, according to Student’s t-test analysis). The data presented are from a representative experiment that was repeated three times with similar results.

Subsequently, we investigated some of the mechanisms underneath this result by analyzing the levels of SA and JA since it is well-known that these phytohormones and their antagonism are crucial for the development of pathogenicity in Arabidopsis (Spoel and Dong, 2008; Grant and Jones, 2009). Pteris et al., 2009). Hormone measurements clearly showed that JA levels were much lower in hpl1 than in Ler (Figure 2A). Conversely, hpl1 showed an earlier induction of SA than Ler (Figure 2B). These data suggest that a non-functional HPL gene influences the JA branch of the oxylipin pathway, leading to lower production of JA when Arabidopsis is challenged with Pseudomonas. This, thus is not related to substrate competition as previously shown in Arabidopsis where ectopic expression of HPL led to lower JA levels upon wounding (Chehah et al., 2006). Reduction of HPL expression in rice and N. attenuata also influenced JA levels but differently: Oshpl3 and ashpl1 had increased JA levels (Haltitschie et al., 2004; Tong et al., 2012), in N. attenuata probably due to crosstalk between the GLV and JA pathway (Allmann et al., 2010).

Since JA-signaling downstream of COI1 occurs via two different branches, regulated by MYC2 or ORA59, we used markers for both branches to study their activation after DC3000 infection. LEC, a leucin-rich gene, was used for the ORA59 pathway since it is induced by methyl-jasmonate and upon ORA59 overexpression (Schröck et al., 2000; Pré et al., 2008), while VSP2 was used for the MYC2 pathway (Abe et al., 2003; Dombrecht et al., 2007). Both VSP2 and LEC transcript levels were much lower in hpl1 than in Ler (Figures 3A,B) concurrent with the lower JA levels. Thus DC3000 activates in Ler, with an active HPL unlike Col-0 (Duan et al., 2005), with which most DC3000 experiments are carried out, both branches of the JA-signaling pathway and antagonistic control of these distinct branches of the JA pathway (Verhaugh et al., 2011) is apparently minor. Transcript levels of the SA-marker PR-1 were higher upon DC3000 infection, similarly in hpl1 and Ler (Figure A1 in Appendix), probably because the differences in SA levels between the two genotypes were not big enough to cause a difference. Thus it seems that the lower JA levels in hpl1 plants leads to less activation of the JA-signaling pathways and renders them less susceptible to DC3000.

A hallmark of basal plant defenses to pathogen infection is the deposition of callose. PAMP-induced callose deposition has recently been defined with essential roles for the DC3000 type III effector HopM1 and COR suppressing callose deposition, the latter being, interestingly, partly COI1-independent (Geng et al., 2012). Our results showed that in hpl1, although with smaller bacterial populations than in Ler, clearly less callose was deposited (Figures 4B,C). Ethylene (ET) signaling is crucial for callose deposition in response to flagellin (Clay et al., 2009). It is possible that ET signaling is less activated in hopM1, leading to less callose deposition. Support for this comes from our complementation studies with the hpll mutant, a response that is largely dependent on ORA59, a TF that integrates JA and ET signaling (Figure 6B). Perhaps related to this is the fact that DC3000 is apparently less effective in preventing cell death in hopM1 than in Ler (Figure 6A), with fewer living cells producing less callose. DC3000 apparently triggers in hopM1 a higher rate of cell death, which is related to higher resistance (Jones and Dong, 2008).

With the aim to overcome the hpll phenotype in response to DC3000 infection, we decided to treat these, and Ler, plants with E-2-hexenal. The pre-treatment with 3 μM E-2-hexenal for 24 h prior to DC3000 infection made hpll plants considerably more effective in preventing cell death in hopM1 than in Ler (Figure 6A), with lower bacterial populations and fewer living cells producing less callose. DC3000 apparently triggers in hopM1 a higher rate of cell death, which is related to higher resistance (Jones and Dong, 2008).
function of proteins involved in the plant defense responses to DC3000, making Arabidopsis more susceptible to this pathogen. A similar effect has been reported for syringolin, a toxin with an unsaturated α,β unsaturated moiety, that makes it a RES, produced by, e.g., Pseudomonas syringae pv. syringae. This toxin specifically inhibits the proteasome in order to suppress host defenses (Groll et al., 2008; Schellenberg et al., 2010).

Analyses of phytohormone levels after treatment of E-2-hexenal and DC3000 infection showed that there were no statistically significant differences in SA and JA levels between control and treatment (Figure A2 in Appendix). So far only in monocots (maize) an increase in JA has been measured after a GLV treatment (Engelberth et al., 2004, Engelberth, 2011). In the JA-signaling pathway COI1 plays a central role and mutants in this gene are blocked in almost all JA responses (Feng et al., 2003; Devoto et al., 2005; Wang et al., 2008). Downstream of COI1, different TFs regulate specific JA-dependent responses. MYC2 and ORA59 are the main players involved. The MYC2-dependent branch is associated with wound response, responses against herbivores and is also regulated by abscisic acid (ABA, Lorenzo et al., 2003). This basic helix-loop-helix (bHLH) transcription factor regulates a large number of JA-responsive genes (Dombrecht et al., 2007), among which VEGETATIVE STORAGE PROTEIN2 (VSP2; Liu et al., 2005).

In the other branch, ORA59 integrates JA and ET signaling (Pré et al., 2008). Interestingly, in spite of the absence of differences in JA and SA levels, the higher susceptibility of Arabidopsis plants to DC3000 after E-2-hexenal treatment was dependent on ORA59. The DC3000 bacterial populations increased only slightly in ORA59 plants after E-2-hexenal treatment as compared to control (35S-GUS) plants (Figure 6B), indicating the relevance of JA signaling, and perhaps ET signaling. A role for MYC2 in this process was excluded based on the fact that myc2 mutants still responded to eugenol E-2-hexenal treatment (Figure 6A).

From the bacterial side we investigated whether the production of COR was necessary to benefit from the E-2-hexenal treatment. For this we employed cor and COR-deficient strains, to infect plants, after the E-2-hexenal or control treatment. The result showed that there was a small but significant increase in bacterial populations of the cor strain after the E-2-hexenal treatment (Figure 7). Nevertheless this difference was much smaller than for DC3000, suggesting that COR is necessary for DC3000 to fully benefit from GLVs.

Our data show that a functional HPL in Arabidopsis promotes susceptibility to DC3000. This effect is partially mediated by ORA59 in the plant and by COR in the bacteria.

The question remains how DC3000 precisely exploits HPL or its products, GLVs or the C24 compounds that are also found in the HPL pathway (Kallenbach et al., 2011), for its benefit. Since it is clear that some herbovirnes can lower HPL transcript levels (Halischke et al., 2004; Schlenken et al., 2012), we propose that HPL may be a target for DC3000 to employ in Arabidopsis, albeit to its own advantage.

ACKNOWLEDGMENTS

We kindly acknowledge Johan Memelink (Leiden University, Netherlands) for providing the ir-ORA59 seeds and Saskia van Wees (University of Utrecht, Netherlands) for myc2 seeds. Alessandra Scala was supported by NWO-AIW grant 818.02.017.

APPENDIX

FIGURE A1 | PR-1 expression is equally induced in Ler and hpl1. PR-1 transcript levels were measured by qRT-PCR in Ler and hpl1 infected with DC3000 48 hpi and normalized for SAND transcript levels. Error bars represent standard error.

FIGURE A2 | E-2-hexenal does not induce changes in JA and SA levels in Ler and hpl1 plants infected with DC3000. (A) JA levels in Ler and hpl1 plants pre-treated with E-2-hexenal or MeOH and subsequently infected with DC3000 (48 hpi). (B) SA levels in Ler and hpl1 plants pre-treated with E-2-hexenal or MeOH and subsequently infected with DC3000 (24 hpi). In both cases the hormone levels in the 10 mM MgSO4 (mock) infiltrated plants are also shown. Nine leaves were harvested, in pools of three from mock-infiltrated or bacteria-infiltrated plants at specified timepoints and used for plant hormone quantification. Bars represent the mean of three independent experiments. Error bars represent standard error. Bars annotated with different letters indicate statistically different hormone levels (P < 0.05, according to ANOVA, followed by a LSD post hoc test).
