Abstract. The Arctic Ocean ecosystem is particularly vulnerable to ocean acidification (OA) related alterations due to the relatively high CO₂ solubility and low carbonate saturation states of its cold surface waters. Thus far, however, there is only little known about the consequences of OA on the base of the food web. In a mesocosm CO₂-enrichment experiment (overall CO₂ levels ranged from ~180 to 1100 µatm) in Kongsfjorden off Svalbard, we studied the consequences of OA on a natural pelagic microbial community. OA distinctly affected the composition and growth of the Arctic phytoplankton community, i.e. the picoeukaryotic photoautotrophs and to a lesser extent the nanophytoplankton thrive. A shift towards the smallest phytoplankton as a result of OA will have direct consequences for the structure and functioning of the pelagic food web and thus for the biogeochemical cycles. Besides being grazed, the dominant pico- and nanophytoplankton groups were found prone to viral lysis, thereby shunting the carbon accumulation in living organisms into the dissolved pools of organic carbon and subsequently affecting the efficiency of the biological pump in these Arctic waters.

1 Introduction

The increase of pCO₂ in the surface ocean (ocean acidification, OA) profoundly affects the seawater carbonate system through well-known chemical reactions, lowering the pH, increasing the concentration of bicarbonate ions, decreasing the availability of carbonate ions and lowering the saturation state of the major shell-forming carbonate minerals. Whereas surface water pH values were still 8.2 just prior to the industrial era, they are 8.11 at present and anticipated to reach 7.8 in the year 2100 (The Royal Society, 2005). This corresponds to CO₂ levels of 380 µatm at present to a projected high of at least 750 µatm by the end of this century.

Changes in carbonate chemistry can be expected to directly affect phytoplankton photosynthesis and subsequently growth because of their dependence on CO₂ supply. Not all algal groups will be equally affected, as certain groups (most notably diatoms) have developed CO₂-concentrating mechanisms (CCMs). However, algal species differ in CCM efficiency (Rost et al., 2008). Non-calculating phytoplankton show, as expected, a range of responses, varying from no effect on growth to stimulating or adverse effect on growth or primary production (Riebesell and Tortell, 2011). Only a few studies have reported on OA-induced changes of phytoplankton community composition (Tortell et al., 2002, Engel et al., 2008; Meakin and Wyman, 2011; Feng et al., 2009), and the ecological consequences of OA on natural phytoplankton dynamics are still understudied.

Furthermore, a major gap in our understanding concerns the transfer of responses from the organism to the community and ecosystem levels. Rose et al. (2009) recently showed that climate change variables (temperature and pCO₂) did affect trophic dynamics during a North Atlantic spring bloom. As a result, predicting the impact of ocean acidification on marine ecosystem dynamics, and consequently biogeochemically cycling, is presently still limited. As pointed out by The Royal Society (2005), marine ecosystems are likely to become less robust as a result of ocean acidification and will be more vulnerable to other environmental changes.
(e.g. temperature increase, light availability, nutrient limitation). Potential restructuring of the phytoplankton community (classes, species and cell size; Falkowski et al., 1998; Boyd and Doney, 2002) as a result of ocean acidification will have direct consequences for grazer communities and organic carbon flow. It may also influence the dominance of grazing over other loss processes such as viral lysis, and consequently the cycling of energy and biogeochemically relevant elements, the ratio of production and respiration of the ocean and the efficiency of the biological pump (Brussaard et al., 1996, 2008; Ruardij et al., 2005; Suttle, 2007). Phytoplankton that are consumed by grazers are channeled to higher trophic levels, whereas viral lysis directly forces the food web towards a more regenerative pathway (Brussaard et al., 2005; Suttle, 2007).

OA and other global climate change-related impacts are most striking in both polar regions, where temperatures and acidities are changing at more than twice the global average (Hoegh-Guldberg and Bruno, 2010). The cold Arctic surface waters allow relatively high CO₂ solubility, making this area particularly vulnerable to OA. The present study is part of a collaborative mesocosm CO₂-enrichment experiment performed in Kongsfjorden off Svalbard, summer 2010, within the framework of the European Project on Ocean Acidification (EPOCA). We present here the microbial community dynamics under the influence of elevated pCO₂ levels and discuss the consequences for the functioning of the pelagic food web.

2 Material and methods

2.1 Study site and experimental set-up

The study was conducted in Kongsfjorden (78°56′2″N, 11°53′6″E), near Ny-Ålesund, Svalbard, between 31 May and 7 July 2010 (day t = 7 to t30, where t0 is the day after the first CO₂ addition). Nine large mesocosms of approximately 50 m³ (15 m below sea level) were moored in the fjord in sets of 3. The experimental set-up, carbon chemistry dynamics and nutrient concentrations throughout the experiment are described in detail by Riebesell et al. (2013), Bellerby et al. (2013) and Schulz et al. (2013). In short, the mesocosms were filled with fjord water (inorganic nutrient concentrations < 0.1, 0.09, 0.2 and 0.7 µM for nitrate, phosphate, silicate and ammonium, respectively) and screened through a 3 mm mesh to eliminate larger organisms on the 1 of June (t−6). The mesocosms were open to the atmosphere but covered with transparent hoods to minimize input of rain and bird droppings. Two of the mesocosms received no CO₂ addition but were treated otherwise the same, representing the present day carbonate chemistry of the fjord (~ 185 µatm at the start of the experiment). The addition of CO₂ was gradual between day t−1 and t4 by pumping CO₂-enriched seawater through a dispersal device which was lowered to about 13 m depth and gently pulled up several times, resulting in an even distribution throughout the water column. The other 7 mesocosms were enriched with CO₂ over a period of several days (t = 1 to t4) in varying amounts, resulting in a range of initial pCO₂ levels from ~ 270 to ~ 1420 µatm (corresponding to pH₇ values of 8.18 to 7.51). Two weeks into the experiment (t13), inorganic nutrients were added to the originally nutrient-poor water in order to stimulate primary production (5 µM nitrate, 0.3 µM phosphate and 2.5 µM silicate for all mesocosms, to simulate the upwelling of deeper, nutrient-rich water to the nutrient-depleted surface water). The one month experiment showed 4 phases: phase 0 represents the period from closing of the mesocosms to the end of the CO₂ manipulations (t = 7 to t13), phase 1 corresponds to the period after CO₂ manipulation until the addition of inorganic nutrients (t4 to t12), phase 2 stands for the period after nutrient addition and until the second chlorophyll minimum (t13 to t21; Schulz et al., 2013), and phase 3 includes the final period until the end of the experiment (t22 to t30). Throughout this study the data are presented using 3 colors (blue, grey and red), representing low, intermediate and high pCO₂ additions. The low pCO₂ addition group contains mesocosms 3, 7 and 2; the intermediate group consists of mesocosms 4, 8 and 1; and the high pCO₂ addition group is made up of mesocosms 6, 5 and 9.

Collective sampling was performed daily in the morning using an integrated water sample (0–12 m). From this water subsamples were obtained for counting phytoplankton, heterotrophic prokaryotes (HP) and viruses. Besides this, we sampled 2–3 times per week for the microzooplankton grazing incubations using a gentle vacuum-driven pump system. Samples were protected against daylight by black plastic bags. In the laboratory the samples were maintained and processed (for grazing assay and counting) at a constant temperature and dimmed light. The abundances of phytoplankton were determined on fresh samples. HP and viruses were fixed for 30 min at 7°C with glutaraldehyde (25 %, EM-grade) at a final concentration of 0.5 % before snap freezing in liquid nitrogen and storage at −80 °C until analysis.

2.2 Microbial abundances

The microbes were enumerated using a bench-top Becton Dickinson FACSCalibur flow cytometer (FCM) equipped with a 488 nm argon laser. The photoautotrophic cells (< 20 µm) were counted fresh and discriminated by their pigment autofluorescence (Marie et al., 1999). Only eukaryotic photosynthetic organisms were detected. Based on their autofluorescence and side scatter signal, the phytoplankton community could be divided into 6 clusters: picophytoplankton I and II, and nanophytoplankton I to IV. Nanophytoplankton III and IV displayed higher side scatter signals than other clusters similar in size. Average cell size of the different clusters was determined by serial gravity filtration of a very small volume of sample (< 10 mL) through different
polycarbonate 47 mm diameter filters (10, 8, 5, 3, 2, 1, 0.8, 0.4 µm) according to Veldhuis and Kraay (2004). Cell sizes of the different clusters ranged between 0.8–2, 2–3, 3–8, 8–10, 5–8 and 3–5 µm diameter for picophytoplankton I, II, and nanophytoplankton I, II, III, and IV, respectively. Assuming the cells to be spherical and containing 0.2 pg C µm⁻³ (Cувель, 2010), cellular carbon was calculated based on the average cell diameters (1.3, 3, 5, 10, 7 and 4 µm, respectively). Estimated cellular carbon contents were 0.18, 2.8, 13.1, 104, 35.8 and 6.7 pg C cell⁻¹ for the 6 phytoplankton clusters, respectively (Veldhuis and Kraay, 2004). Net growth and loss rates of phytoplankton were derived from exponential regression analysis of the cell abundances.

The abundances of heterotrophic prokaryotes and viruses were determined from fixed, frozen samples according to Marie et al. (1999) and Brussaard (2004), respectively. In short, thawed samples were diluted with Tris-EDTA buffer (10 mM Tris-HCl and 1 mM EDTA, pH 8) and stained with the green fluorescent nucleic acid-specific dye SYBR-Green I (Molecular Probes, Invitrogen Inc.), for a final concentration of 1 × 10⁻⁴ (HP) or 0.5 × 10⁻⁴ (viruses) of the commercial stock, in the dark at room temperature for 15 and 10 min, respectively. HP and viruses were discriminated in bivariate scatter plots of green fluorescence versus side scatter. Final counts were corrected for a blank consisting of TE-buffer and SYBR-Green I prepared and analysed in an identical manner to the samples. Two HP clusters (HDNA – high DNA fluorescent – and LDNA – low DNA fluorescent) and 5 viral groups (V1–V5) were distinguished.

2.3 Microzooplankton grazing

Microzooplankton grazing of phytoplankton was determined using the dilution method of Landry and Hassett (1982). In short, whole seawater samples were sieved through a 200 µm mesh to remove mesozooplankton, after which the sample was combined with 0.45 µm filtered seawater (0.45 µm Sartopore capsule filter, containing a 0.8 µm pre-filter) over a dilution series of 20, 40, 70 and 100 % to create a gradient in microzooplankton grazing pressure. All treatments were set up in triplicate in clear 1.2 L polycarbonate bottles. The bottles were incubated at in situ temperature and natural light. Subsamples were taken at 0 and 24 h, and phytoplankton abundance was enumerated immediately by FCM. Phytoplankton growth rates were plotted against the level of dilution, and model 1 regression analysis was performed to obtain the actual microzooplankton grazing rate (slope) and apparent phytoplankton growth rate in the absence of grazing (intercept y-axis). All seawater handling was performed at in situ temperature and under dim light conditions using Nitrile gloves. For logistical reasons we could only handle two dilution assays at a time. We choose to sample mesocosm 3, representing present time pCO₂ level, as reference for mesocosm 8 (intermediate pCO₂ levels) and mesocosm 5 (high pCO₂ levels), which each were sampled alternately. Microzooplankton grazing on nanophytoplankton II-IV failed due to the low whole water abundances (<200 mL⁻¹).

2.4 Statistics

For the statistical tests we used SYSTAT version 13.00.05 (SYSTAT Software, Inc. 2009, San Jose, CA). The hypothesis that there was no difference in growth rates of microbes in diverse time frames during the mesocosm experiment was tested using one-way ANOVA. Testing overall differences in standing stock of diverse flow cytometric clusters during different time periods was performed using ANOVA with the square root-transformed abundances as the dependent variable, mesocosm as factor, and the sampling day as covariate. To test the specified hypothesis, contrasts in the post hoc hypothesis tests were used. The grazing rates were calculated in Excel, including the standard error of the grazing rates (i.e. standard error of the estimated slope of the regression line). P values indicate if the grazing rates differ significantly from zero.

3 Results

3.1 Phytoplankton abundances and net growth

The abundance of each phytoplankton cluster is presented in Fig. 1. Total phytoplankton abundance was strongly dominated by picophytoplankton I (Fig. 1a), generally making up more than 90 % of the total count, except for r1 to r11 when their share declined to 60 % due to a bloom of nanophytoplankton (Fig. 1c). Picophytoplankton I showed a steady increase until t18, after which the bloom declined sharply (Fig.1a). The net growth rates during phase 1, derived from the standing stock and calculated using the natural logarithm, were on average 0.14 ± 0.03, 0.15 ± 0.03 and 0.17 ± 0.02 for the low, intermediate and high pCO₂ mesocosms, respectively. During phase 2, after inorganic nutrient addition, the net growth rates of the picophytoplankton I were slightly higher, ranging from 0.14 to 0.24 d⁻¹ (no significant correlation with pCO₂, however). Highest net peak abundances, i.e. 1.1–1.5 × 10⁵ cells mL⁻¹, were recorded for the high pCO₂ mesocosms 5, 6, and 9 (ANOVA, p < 0.000). Picophytoplankton II increased until t7 at a net growth rate between 0.30 and 0.38 d⁻¹ (Fig. 1b). The highest abundances of 3.5–4.9 × 10⁵ cells mL⁻¹ during phase 1 were observed for the intermediate and low pCO₂ mesocosms (ANOVA, p < 0.000).

Nanophytoplankton I increased steeply from the start of the experiment, growing at net growth rates between 0.51 and 0.55 d⁻¹ (with the exception of mesocosm 4 showing a growth rate of 0.42 d⁻¹), and peaked at t4–6 with maximum abundances between 1.6 and 1.8 × 10⁶ cells mL⁻¹ (Fig. 1c). A second increase was found during the last week of the experiment with highest abundances typically in the higher pCO₂ mesocosms. Nanophytoplankton II were present in
low numbers (generally below 150 cells mL\(^{-1}\)) and could no longer be detected in either the mesocosms or the natural fjord water from \(t\)10 onwards (Fig. 1d). Around the same time (\(t\)6), a new phytoplankton population, nanophytoplankton III, appeared that was undetectable until then (Fig. 1e). It remained present throughout the duration of the experiment at a rather stable concentration (\(<150\) cells mL\(^{-1}\)), with significantly higher algal numbers for the high \(p\)CO\(_2\) mesocosms during phase 2 and 3 (ANOVA, \(p < 0.000\)). Nanophytoplankton IV showed similar algal concentrations, with significantly higher abundances during phase 3 in the high \(p\)CO\(_2\) addition mesocosms (Fig. 1f; ANOVA, \(p < 0.000\)).

Figure 2 shows the phytoplankton (\(<20\) µm) cellular carbon (algal POC). The first maximum at \(t\)5 is due to the peak in nanophytoplankton around that time (Fig. 2a). Despite their relatively low numbers, their larger size results in algal POC concentrations similar to or higher than that of the more abundant (up to 70-fold higher cell abundances) but very small picoeukaryotic algae that are responsible for the second maximum of algal POC (Fig. 2b).

### 3.2 \(p\)CO\(_2\)-related phytoplankton trends

As expected, all mesocosms resembled each other for microbial abundances during the initial phase 0 (\(t\)7 to \(t\)3). Shortly after completing \(CO\(_2\) additions (at \(t\)7; phase 1), the standing stock of picophytoplankton II in the three high \(p\)CO\(_2\) mesocosms, 5, 6 and 9, showed a negative response (Fig. 3a). This response was, however, not maintained and even reversed after nutrients were added at \(t\)13. It has to be noted that picophytoplankton II was made up by 3 subpopulations that were hard to separate. A weak positive correlation with \(p\)CO\(_2\) during phase 1, thus prior to nutrient addition, was only observed for picophytoplankton I (\(y = 16.6x + 20963, r^2 = 0.516\)). Upon the addition of inorganic nutrients (phase 2),
picophytoplankton II became dominated by one of those sub-populations. Interestingly, the peak abundances of picophytoplankton I at \( t_{18} \) correlated strongly and positively with \( p\text{CO}_2 \) (Fig. 3b). Net growth rates until \( t_{18} \) were on average 0.15–0.20 \( \text{d}^{-1} \) (no significant trend with \( p\text{CO}_2 \) observed). However, a statistically significant and positive relationship with \( p\text{CO}_2 \) was found for the cell abundances of picophytoplankton II and nanophytoplankton I (Figs. 3c and d; \( p = 0.008 \)). Nanophytoplankton III and IV furthermore showed positive correlations with \( p\text{CO}_2 \) only until 600 µatm (\( r^2 \) of 0.903 and 0.610, respectively), however, the low cell abundances (<150 mL\(^{-1} \)) caution for over-interpretation (higher statistical error). Notwithstanding, the positive correlation between phytoplankton standing stock and \( p\text{CO}_2 \) was clearly illustrated by total algal POC (Fig. 4).

Within phase 1 of the experiment (\( t_{4} \) to \( t_{13} \)), the net loss rates during the decline of the nanophytoplankton I peak (\( t_{6} \) to \( t_{13} \)) were negatively correlated with \( p\text{CO}_2 \), i.e., lower net loss rates at higher \( p\text{CO}_2 \) levels (from \(-0.15 \text{d}^{-1} \) at high \( p\text{CO}_2 \) to \(-0.3 \text{d}^{-1} \) at low \( p\text{CO}_2 \); Fig. 5a). During the decline of the picophytoplankton II bloom (\( t_{7} \) to \( t_{22} \)) the highest \( p\text{CO}_2 \) mesocosms also showed reduced net loss rates (on average \(-0.10 \pm 0.04 \text{d}^{-1} \) as compared to \(-0.19 \pm 0.03 \text{d}^{-1} \) for the other mesocosms; Fig. 5b). In contrast, the net loss rates after the bloom of picophytoplankton I (\( t_{18} \)–\( t_{26} \)) show a positive correlation with \( p\text{CO}_2 \) when excluding mesocosm 4, which had already declined before that period (on average \(-0.32 \pm 0.1 \text{d}^{-1} \) for the mesocosms with \( p\text{CO}_2 \geq 600 \text{µatm} \) and \(-0.19 \pm 0.07 \text{d}^{-1} \) for \( p\text{CO}_2 \leq 600 \text{µatm} \); Fig. 5c). At the end of the experiment (\( t_{27} \), the picophytoplankton I show a negative correlation with \( p\text{CO}_2 \), however, we argue below that at this stage into the experiment such a correlation is the indirect effect of viral lysis and grazing dynamics.

### 3.3 Phytoplankton viruses and microzooplankton grazing

The viral community could be discriminated into 5 distinct clusters, of which two (V4 and V5) are considered most likely algal viruses (Fig. 6; Brussaard and Martínez Martínez, 2008). The abundance of viruses V4 started to increase upon the development of the nanophytoplankton I bloom and showed its strongest increase concomitantly with the decline of this phytoplankton group (Figs. 1c and 6a). Moreover, V5 increased sharply the moment the bloom of picophytoplankton I declined (\( t_{18} \); Figs. 1a and 6b), indicating a regulating role on viruses of the dynamics of also this phytoplankton population.

Microzooplankton grazing rates (Table 1) showed high grazing on picophytoplankton I during the first days of the experiment (phase 0; around 0.45 ± 0.14 \( \text{d}^{-1} \)). Grazing rates dropped after phase 0 down to 0.1–0.2 \( \text{d}^{-1} \). No correlation with \( p\text{CO}_2 \) was observed. For unknown reasons, the dilution assay during the first half of the experiment (phase 0 and 1) did not provide good grazing data for the picophytoplankton II. During the second half of the experiment (phase 2 and 3), grazing on picophytoplankton II was substantial (on average 0.39 ± 0.30 \( \text{d}^{-1} \)), and although grazing rates seem somewhat higher at high \( p\text{CO}_2 \), the low number of grazing experiments does not validate a statistically significant conclusion. Microzooplankton grazing on nanophytoplankton I was on average 0.44 ± 0.36 \( \text{d}^{-1} \) throughout the experiment, with high rates during phase 2 (0.81 ± 0.26 \( \text{d}^{-1} \) vs. 0.28 ± 0.40 \( \text{d}^{-1} \) for other phases).

### 3.4 HP and viral dynamics

The abundance of HP in all mesocosms dropped abruptly during the first week (by 1.5 × 10^6 mL\(^{-1} \); Fig. 7a), which was fully due to the decline in the high nucleic acid (HDNA) HP population. The % HDNA HP dropped from around 80 to 40–55 % at \( t_{7} \) (Fig. 7b). Viruses increased in abundance around 1 × 10^7 mL\(^{-1} \) (Fig. 8a). The concomitant decline of HP and increase in viruses resulted in a steeply increasing total virus to prokaryote ratio (VPR), from 25 up to 150 (Fig. 8b). After \( t_{7} \) the total HP community increased steadily again (Fig. 7a). The % HDNA HP also increased again up to a maximum of 70 % at \( t_{14} \) (Fig. 7b), after which it decreased steadily, resulting in an equal contribution of HDNA and LDNA HP towards the end of the experiment (phase 3). HP net growth rates, derived from \( t_{5} \) to the end of the experiment, correlated negatively to \( p\text{CO}_2 \), which consequently resulted in a negative correlation between HP abundance at \( t_{28} \)
and $pCO_2$ levels (Fig. 7c). No such trend was found for virus abundances. However, the slopes of the linear regression of viruses versus HP per mesocosm plotted against $pCO_2$ levels resulted in a linear correlation (Fig. 8c), which suggests a stronger impact of viruses on HP dynamics at higher $pCO_2$.

### Table 1. Microzooplankton grazing rates on phytoplankton (d$^{-1}$) for 3 mesocosms representing low, intermediate (mid) and high $pCO_2$ levels. Mesocosm M3 (low, i.e. present time $pCO_2$) was sampled as reference to mesocosm M5 and M8. Failed assays for specific phytoplankton clusters are indicated by −. Standard error between parentheses. Statistical significance indicated by * $p = 0.1–0.05$; ** $p = 0.05–0.01$; *** $p = 0.01–0.001$; and **** $p = 0.001–0$.

### Fig. 3. Phytoplankton cell abundance versus actual $pCO_2$ for picophytoplankton II on t7 (a), picophytoplankton I on t18 (b), picophytoplankton II on t18 (c), and nanophytoplankton I on t18 (d). For (b–d) the CO$_2$ concentrations plotted were the averages of t8 to t18. For color and symbol coding, see Fig. 1. Linear regression statistics provided in plots.

and $pCO_2$ levels (Fig. 7c). No such trend was found for virus abundances. However, the slopes of the linear regression of viruses versus HP per mesocosm plotted against $pCO_2$ levels resulted in a linear correlation (Fig. 8c), which suggests a stronger impact of viruses on HP dynamics at higher $pCO_2$.

### 4 Discussion

The Arctic Ocean ecosystem is particularly vulnerable to OA related alterations due to the relatively high CO$_2$ solubility and low carbonate saturation states of its cold surface waters. Thus far, however, there is only little known about the consequences of OA on the base of the food web. In a mesocosm CO$_2$-enrichment experiment (overall CO$_2$ levels ranged from ∼180 to 1100 µatm) in Kongsfjorden off Svalbard, we studied the consequences of OA on a natural pelagic microbial
community. Overall, our results show that elevated CO₂ stimulated the growth of the smallest size range of primary producers, thereby substantially affecting the structure and functioning of the pelagic food web in the future.

4.1 Phase 0

The initial phase of the experiment showed an increase in standing stock of the phytoplankton clusters picophytoplankton II (2–3 μm diameter) and nanophytoplankton I (3–8 μm diameter). For nanophytoplankton I the gross growth rate based on the net growth rates and grazing rate (dominant loss factor) compares well with the 0.87 d⁻¹ gross growth rate obtained by ¹³C-uptake for a phytoplankton group that included nanophytoplankton (De Kluijver et al., 2013). Inorganic nutrients were depleted due to the spring bloom preceding our experiment, and thus, the smaller-sized phytoplankton had a competitive advantage by growing on remineralised ammonia and inorganic phosphate (Schulz et al., 2013). Furthermore, utilization of organic nutrients and mixotrophy may also have allowed growth by these phytoplankton groups (Schulz et al., 2013). Light microscopy data showed that nano-sized (around 5 μm cell diameter, thus potentially belonging to nanophytoplankton I) *Pseudopedinella* sp., a known mixotroph, peaked around t4 (A. Stuhr, personal communication, 2012). Another mixotroph chrysophyte, i.e. *Ochromonas* sp., also developed during phase 0 and into phase I (A. Stuhr, personal communication, 2012). However, expressed in organic carbon, these chrysophytes were not the dominant nanoeukayotes. Phytoplankton pigment analysis showed dominance of Prasinophyceae and Haptophyceae (Schulz et al., 2013), which are known to consist largely of pico- and nanophytoplankton, respectively. Members of Prasinophyceae have been found to be the most abundant picophytoplankton (Zhu et al., 2005), although recently Cuvelier et al. (2010) found that picoprymnesiophytes (Haptophyceae) may also contribute to global picophytoplankton

**Fig. 5.** Specific growth rates determined from the net phytoplankton abundances versus pCO₂. Nanophytoplankton I from t6–t13 (a), picophytoplankton II from t7 to t22 (b), and picophytoplankton I from t18–t26 (c). A negative growth rate indicates cell loss. The CO₂ concentrations plotted were the averages for the specific time periods indicated. For color and symbol coding, see Fig. 1. Linear regression statistics provided in plots.
biomass. Recently, dominance of picophytoplankton has also been shown in the perennially cold ocean in the Canadian Arctic during summer (>70% of total cell count; Tremblay et al., 2009). Additionally, some diatoms were still present, but these were typically larger than detectable by the flow cytometer used in this study (Schulz et al., 2013).

We noted a clear decline in the HP standing stock during the period of CO$_2$ manipulations (of 0.2 × 10$^5$ HP mL$^{-1}$ d$^{-1}$) that matched the decline in HP production (Motegi et al., 2013) and was likely due to viral lysis. Virus-mediated mortality rates were higher than throughout the rest of the experiment, i.e. 90% of standing stock lysed d$^{-1}$ vs. 23% d$^{-1}$, whereas grazing by heterotrophic nanoflagellates accounted for about one third of the mortality of the standing stock (W. Weinbauer, personal communication, 2012). The estimated burst size was on average 7 viruses per lysed bacterium cell (estimated from the net loss of HP and net production of viruses), which may seem somewhat low (see review by Parada et al., 2006), but Middelboe et al. (2002) have observed similar burst sizes in Arctic water during summer and Boras et al. (2010) have reported a burst size of 1–59 viruses per bacterium in north Svalbard during summer. Interestingly, specifically the HDNA HP were affected. Phage proliferation has been found to depend on host metabolism (e.g. HP host generation times; see review by Weinbauer, 2004), and HDNA HP have been reported to represent the metabolically active members of the microbial community (Lebaron et al., 2001). However, some contrasting studies did show that LDNA HP can also be an active part of the microbial population (Zubkov et al., 2001; Brussaard et al., 2005; Wang et al., 2009). Preferential grazing on HDNA HP has been implied (Gasol et al., 1999; Vaqué, 2001), although cell size instead of metabolic activity might have been the underlying reason. Still, the selective loss of HDNA HP due to viral lysis has not been, to our knowledge, yet reported.

4.2 Phase 1

This phase is the only period in which the sole effect of the CO$_2$ treatment could be determined as nutrients were not added yet ($t$13). Phase 1 was dominated in algal POC by nanophytoplankton, peaking around $t$5. The study by Schulz et al. (2013) showed that the Haptophyceae was the principal algal class. Although no obvious correlation between the peak abundances and $p$CO$_2$ was recorded, we did find a significant negative correlation of the net loss rates (obtained from the decline in net abundances) with $p$CO$_2$. The relatively high net loss rates for nanophytoplankton I in the low CO$_2$ mesocosms (0.30 d$^{-1}$ as compared to 0.20 d$^{-1}$ for the high CO$_2$ mesocosms) corresponded well with the higher microzooplankton grazing rates found at the low CO$_2$ level (0.35 d$^{-1}$ vs. 0.20 d$^{-1}$ at high $p$CO$_2$). OA has been reported not to affect microzooplankton abundance or grazing activity (Suffrian et al., 2008), however in contrast to our study, neither phytoplankton composition nor succession differed between their CO$_2$ treatments (Riebesell et al., 2007). Still, OA during the present study did not significantly affect the diversity of the protozooplankton (ciliates and heterotrophic dinoflagellates), indicating to a high tolerance of this Arctic protozooplankton community to changes in $p$CO$_2$/pH (Aberle et al., 2013). Although grazing on nanophytoplankton I matched the net loss rates, viral lysis also accounted for substantial loss (based on increase of virus V4 and concurrent decline of nanophytoplankton I), which implies that the nanophytoplankton still grew but that the higher loss rates resulted in the decline of the algal bloom. De Kluijver et al. (2013) indeed still recorded $^{13}$C utilization by the nanophytoplankton during $t$5 to $t$10.

Assuming half the net decline in nanophytoplankton I abundance to be due to viral lysis, we found viral burst sizes (i.e. the number of newly produced viruses released per lysing host cell; derived from the net increase in V4 abundance and half of the net decline in algal host abundance) of 540–764 for the different mesocosms. The literature shows comparable burst sizes for nanophytoplankton host-virus model systems from the Haptophyceae class, e.g. 350–600 for *Phaeocystis globosa* and *P. pouchetti* and
Fig. 7. Temporal development of heterotrophic prokaryotes HP (a) and HDNA HP (b). The abundance of HP at t28 versus pCO2 (average of t8 to t27) is plotted in (c). For color and symbol coding, see Fig. 1. For (c), the linear regression statistics are provided in plot.

Fig. 8. Temporal dynamics of total viruses (a) and the virus to HP ratio (b). Furthermore, the slope of viruses versus HP, thus representing the average number of viruses per HP, for each mesocosm is plotted versus the concurrent pCO2 (averaged over t8 to t27) in (c). For color and symbol coding, see Fig. 1. For (c), the linear regression statistics are provided in plot.

400–1000 for Emiliania huxleyi (see review by Brussaard and Martínez Martínez, 2008).

The utilization of the organic matter released by viral lysis of the HP (phase 0) and the nanophytoplankton (phase 1) resulted in a steady increase in HP abundance after t5. Based on half of the nanophytoplankton lost due to viral lysis, a HP carbon conversion of 12 fg C cell\(^{-1}\) (Fukuda et al., 1998), a HP growth efficiency of 30% (Motegi et al., 2013) and taking 50% mortality of the heterotrophic HP into account (Motegi et al., 2013), we estimated that the cellular carbon released by viral lysis (about 30 µg C L\(^{-1}\)) sustained about a third of the gross HP carbon demand during phase 2. Extracellular enzyme activities and bacterial protein production indeed increased already during phase 0 and peaked during t5 to t10 (Piontek et al., 2013), concomitantly with the virally induced decline in nanophytoplankton I.

The abundance of picophytoplankton II peaked at t7 but was significantly (ANOVA \(p < 0.000\) lower for the high CO\(_2\) mesocosms (\(~650–1100\) µatm). It is unclear whether these algae became negatively affected in their growth at the higher future CO\(_2\) levels or the loss rates for the high pCO\(_2\) mesocosms were enhanced (grazing estimates on picophytoplankton II during this phase failed for the low pCO\(_2\) mesocosm). Hopkins et al. (2010) reported a similar finding for a mesocosm experiment in a fjord in Norway, showing lower
abundances of large picophytoplankton under high \( p\text{CO}_2 \) (750 \( \mu \text{atm} \)) than in the present day \( p\text{CO}_2 \) enclosure. Still, picophytoplankton II formed a complex cluster with 2–3 subpopulations that could not be separated from each other. A shift to one subpopulation in response to elevated \( p\text{CO}_2 \) may also have been responsible for the obtained results.

During phase 1 the abundances of the small-sized picophytoplankton I (average 1.2 \( \mu \text{m} \) cell diameter) increased steadily at 0.15 ± 0.03 \( d^{-1} \) (not significantly different from each other). Correcting for grazing loss, the gross growth rates were overall 0.1 \( d^{-1} \) higher. Already prior to nutrient addition, a weak positive correlation between abundance and \( p\text{CO}_2 \) emerged, suggesting that elevated \( p\text{CO}_2 \) stimulated the growth of these very small-sized phytoplankton (0.8–2 \( \mu \text{m} \)). The trend developed strongly into phase 2 (see Sect. 4.3), emphasizing that elevated \( p\text{CO}_2 \) stimulates growth and nutrient utilization (Schulz et al., 2013) leading to enhanced production of the smallest size range of primary producers.

### 4.3 Phase 2

Phase 2 represents the initial period upon the addition of inorganic nutrients, allowing for potential growth of larger-sized phytoplankton. Elevated \( p\text{CO}_2 \) in combination with nutrient addition stimulated the growth of the smaller-sized phytoplankton, as shown by the positive correlation of algal POC at \( t \) 18 with \( p\text{CO}_2 \). These results were supported by the higher uptake rates of the added inorganic nutrients for the highest \( p\text{CO}_2 \) mesocosms (Schulz et al., 2013). Interestingly, the prevailing group of algae during this period was still the picophytoplankton (particularly cluster I) and to a lesser extent the nanophytoplankton. Algal pigment analysis and light microscopic screening indicated that Prasinophyceae was the dominant algal class, and larger-sized phytoplankton like diatoms were largely absent still (Schulz et al., 2013).

Our results clearly show that the very small-sized picophytoplankton became dominant under increased \( p\text{CO}_2 \) levels, indicating that this group does not or still inefficiently applies carbon concentrating mechanisms (CCMs). Diffusion of \( CO_2 \) is typically not expected to limit photosynthesis in the very small-sized phytoplankton (Giordano et al., 2005), although CCMs were identified for the picophytoplankter *Micromonas pusilla* (Worden et al., 2009). Yet, despite their small size (and thus large surface to volume ratio) their diffusive \( CO_2 \) uptake seems insufficient and their \( CO_2 \) sensitive photosynthesis benefitted from elevated \( p\text{CO}_2 \). Only a small response to OA (e.g. 10 %; The Royal Society, 2005 and references therein) can still result in dominance over time under the assumptions that the loss factors (grazing, viral lysis) do not show direct responses to elevated \( p\text{CO}_2 \) and other growth variables are not limiting the growth. We found no evidence that grazing or viral lysis rates were directly affected by elevated \( p\text{CO}_2 \) levels, and nutrients and irradiance were non-limiting at the time. The higher abundances of picophytoplankton I at high \( p\text{CO}_2 \) resulted thus from somewhat enhanced growth rates. Paulino et al. (2008) reported an increased abundance of picophytoplankton in a high \( CO_2 \) mesocosm; however, this was towards the end of the experiment when all nutrients were depleted. During another Norwegian fjord mesocosm experiment, still nutrient-replete, the total number of small-sized picophytoplankton did not change under increased \( p\text{CO}_2 \) (750 \( \mu \text{atm} \); Hopkins et al., 2010; Newbold et al., 2012). The abundances based on quantitative PCR of specifically the picophytoplankter *Micromonas pusilla*, nevertheless, enhanced significantly (Meakin and Wyman, 2011). A similar trend was observed a few years earlier at the same location, time of the year and experimental set-up, this time based on a *M. pusilla*-like flow cytometric signature (Engel et al., 2008). Meakin and Wyman (2011) showed that the picophytoplankter *Bathycoccus* (also belonging to the Prasinophyceae) was not affected by the increased \( CO_2 \) concentrations. Although we have no knowledge of the actual species that are represented by our flow cytometric clusters, our data show (1) the dominance of the picoeukaryotic phytoplankton in polar waters and (2) the potential ecological importance this group will have in future oceans.

High grazing pressure kept the abundances of nanphytoplankton I under control during phase 2 (on average 0.81 ± 0.26 \( d^{-1} \)). Our data suggest that grazing was not affected by \( p\text{CO}_2 \) (a relationship with \( p\text{CO}_2 \) could not be tested for shortage of grazing rates in the high \( CO_2 \) mesocosms) and viral lysis was not a substantial loss factor at the time, implying that the higher standing stock of the nanphytoplankton I under elevated \( CO_2 \) was also due to higher growth rates (as for the picophytoplankton I).

For the picoeukayotes I viral lysis was the dominant loss factor (0.2–0.3 \( d^{-1} \) while grazing < 0.1 \( d^{-1} \), with the steepest increase of virus population V observed for the highest \( p\text{CO}_2 \) mesocosms (in agreement with the strongest decline of picophytoplankton I at these \( CO_2 \) levels). Estimated burst sizes ranged between 119 and 245 (derived from the net increase in V5 abundance and net decline in algal host abundance), matching the published values for prasinophyte picophytoplankton host-virus model systems (e.g. 72–360 for *Micromonas pusilla*; Waters and Chan, 1982; Baudoux et al., 2008). The resultant release of cellular organic carbon due to viral lysis of the picophytoplankton I increased with \( CO_2 \) level, i.e. 7, 10 and 20 \( \mu \text{g C L}^{-1} \) for the low, intermediate and high \( p\text{CO}_2 \) mesocosms. Based on the HP net growth rate of 0.2 × 105 cells mL\(^{-1} d^{-1}\), a growth efficiency of 30 % and low mortality (Motegi et al., 2013), viral lysis accounted for 15 to 42 % of the gross HP C demand.

### 4.4 Phase 3

Despite the enhanced release of the lysing algal cells in the highest \( p\text{CO}_2 \) mesocosms that continued into phase 3, the HP standing stock was significantly lower at elevated \( CO_2 \) (ANOVA, \( p < 0.000 \)). We speculate that this may have been
due to higher viral lysis rates as a result of higher VPR and therefore encounter rate.

During this last phase of the experiment, picophytoplankton were still most abundant but the biomass share of the nanophytoplankton became more important, equaling picophytoplankton. Schulz et al. (2013) showed that the Haptophyceae, containing many nanoeukaryotic phytoplankton species, increased in abundance during this phase. The same authors showed, furthermore, that larger-sized photoautotrophs such as the Dinophyceae became an important group and were positively correlated to elevated CO$_2$. In contrast, the growth of diatoms and Chlorophyceae was reduced at elevated CO$_2$, most likely due to diminished nutrient availability (inorganic nutrients became depleted during the second half of Phase 3). Species in these phytoplankton classes often have efficient CCMs that allow for optimal photosynthesis and growth at ambient (and past) CO$_2$ concentrations and, therefore, are not (or only minimally) affected by increased CO$_2$ levels (Giordano et al., 2005; Engel et al., 2008; Rost et al., 2008).

5 Conclusions

The most prominent finding of our study is the evident impact of OA on the composition and growth of the Arctic phytoplankton community, i.e. the picoeukaryotic photoautotrophs and to a lesser extent the nanophytoplankton prospered. This mesocosm experiment took into account at least 4 of the 7 future research recommendations stated by Rost et al. (2008), namely it mimicked the environmental conditions as closely as possible, was community based (microbial food web), involved the interactive effects of multiple environmental variables in combination with CO$_2$, and tried to unravel the underlying mechanisms for the observed responses by taking into account loss factors such as grazing and viral lysis. These aspects in combination with our focus on the smaller-sized phytoplankton contributed largely to a more detailed and inclusive understanding of ecological responses to changes in CO$_2$.

A shift towards the smallest phytoplankton as a result of OA will have direct consequences for the structure and functioning of the pelagic food web and thus for the biogeochemical cycles. Due to the very small cell size, one or two additional trophic levels of smaller grazers are evident, which will, as compared to the more traditional food chain (large phytoplankton, suspension-feeding zooplankton and fish), result in reduced transfer of matter and energy to higher predators and increased importance of the microbial food web. Furthermore, the dominant pico- and nanophytoplankton groups were found prone to viral lysis, thereby shunting the carbon that enters the biological pool via photosynthesis from carbon accumulation in living organisms into the dissolved pools of organic carbon (Suttle, 2007). Microbial communities incorporate these pools, thereby converting much of it to CO$_2$ again by respiration and subsequently influencing the efficiency of the biological pump (Brussaard et al., 2008).

The here discussed ecological changes by OA do not stand alone as global climate change impacts the polar waters also through temperature rise, shift in wind, precipitation and circulation (Schofield et al., 2010). Phytoplankton growth-relevant factors such as light, pCO$_2$, temperature, nutrient availability and salinity are all under change due to global warming. The increment in surface water temperature will reduce the solubility of CO$_2$ in the Arctic seawater, and the mean cell size of the phytoplankton community (Daufresne et al., 2009). Moreover, increased surface water temperature and glacier and sea-ice melt will strengthen vertical stratification, which in the Canadian Arctic waters has been reported to stimulate picophytoplankton and reduce nanophytoplankton abundance (Li et al., 2009). Thus, in the global climate-driven changing Arctic Ocean, the smallest phytoplankton are expected to flourish as a general result of OA that is further reinforced in summer by increased temperature-imposed vertical stratification.

Acknowledgements. This work is a contribution to the “European Project on Ocean Acidification” (EPOCA), which received funding from the European Community’s Seventh Framework Programme (FP7/2007-2013) under grant agreement no. 211384. The research leading to these results has also received funding from the European Union Seventh Framework Program (FP7/2007-2013) under grant agreement no. 228224, MESOARQA. We gratefully acknowledge the logistical support of Greenpeace International for its assistance with the transport of the mesocosm facility from Kiel to Ny-Ålesund and back to Kiel. We also thank the captains and crews of M/V ESPERANZA of Greenpeace and R/V Viking Explorer of the University Centre in Svalbard (UNIS) for assistance during mesocosm transport and during deployment and recovery in Kongsfjorden. We thank the staff of the French–German Arctic Research Base at Ny-Ålesund (AWIPEV), in particular Marcus Schumacher, for on-site logistical support. We are indebted to Richard Bellerby for providing DIC data, Sebastian Krug for general support and Jan Czerny for his advice on the sampling of the mesocosms for phytoplankton losses. We finally thank Maarten van Loon for arranging accommodation at the Dutch Station.
