Abstract. The potential effect of ocean acidification (OA) on seawater halocarbons in the Arctic was investigated during a mesocosm experiment in Spitsbergen in June–July 2010. Over a period of 5 weeks, natural phytoplankton communities in nine ~50 m³ mesocosms were studied under a range of pCO₂ treatments from ~185 µatm to ~1420 µatm. In general, the response of halocarbons to pCO₂ was subtle, or undetectable. A large number of significant correlations with a range of biological parameters (chlorophyll a, microbial plankton community, phytoplankton pigments) were identified, indicating a biological control on the concentrations of halocarbons within the mesocosms. The temporal dynamics of iodomethane (CH₃I) alluded to active turnover of this halocarbon in the mesocosms and strong significant correlations with biological parameters suggested a biological source. However, despite a pCO₂ effect on various components of the plankton community, and a strong association between CH₃I and biological parameters, no effect of pCO₂ was seen in CH₃I. Diiodomethane (CH₂I₂) displayed a number of strong relationships with biological parameters. Furthermore, the concentrations, the rate of net production and the sea-to-air flux of CH₂I₂ showed a significant positive response to pCO₂. There was no clear effect of pCO₂ on bromocarbon concentrations or dynamics. However, periods of significant net loss of bromoform (CHBr₃) were found to be concentration-dependent, and closely correlated with total bacteria, suggesting a degree of biological consumption of this halocarbon in Arctic waters. Although the effects of OA on halocarbon concentrations were marginal, this study provides invaluable information on the production and cycling of halocarbons in a region of the world’s oceans likely to experience rapid environmental change in the coming decades.

1 Introduction

Volatile marine halocarbons are produced via a range of biological and photochemical processes in the surface ocean, resulting in a strong flux to the marine atmosphere. Production processes include direct biological synthesis by phytoplankton, bacteria and macroalgae (Tokarczyk and Moore, 1994; Tait and Moore, 1995; Moore et al., 1996; Manley and Cuesta, 1997; Scarratt and Moore, 1998; Amachi et al., 2001; Hughes et al., 2006), and indirect production through reactions between dissolved organic matter and light (Moore and Zafiriou, 1994; Happell and Wallace, 1996; Richter and Wallace, 2004) and/or ozone (Martino et al., 2009). Seawater concentrations of halocarbons are also controlled by a number of loss processes, including hydrolysis and nucleophilic attack (Zafiriou, 1975; Elliott and Rowland, 1993), photolysis (Jones and Carpenter, 2005; Martino et al., 2005) and bacterial assimilation (King and Saltzman, 1997; Goodwin et al., 1998, 2001). The resultant surface ocean halocarbon pool undergoes sea–air gas exchange, a flux which constitutes the most important source of natural halogens to the atmosphere. Halocarbons are rapidly oxidised in the atmosphere.
to produce reactive radicals (I, IO, Br, BrO) which exert an important control on ozone (Chameides and Davis, 1980; Solomon et al., 1994; Davis et al., 1996; Read et al., 2008), and act as condensation nuclei for the growth of larger particles and clouds with the potential to influence global climate (O’Dowd et al., 2002).

In the Arctic, atmospheric halogen species are implicated in ozone (O3) depletion events (ODEs) – dramatic losses of tropospheric ozone that occur following the polar sunrise. ODEs are initiated and catalysed by photochemistry that converts inert halide salt ions (e.g. Br−) into reactive halogen species (e.g. Br and BrO). The most extensive ODEs occur over the frozen Arctic Ocean, as sea ice surfaces, brine and frost flowers represent the main source of inorganic bromine during these events (see Simpson et al., 2007 for review). Halocarbons are considered to play an important role in both the initiation and/or the termination of Arctic reactive halogen chemistry (Simpson et al., 2007). Furthermore, results of modelling studies indicate that iodocarbons such as diiodomethane (CH2I2) have a significantly greater O3 depletion effect (per molecule) than the addition of further sea-salt derived Br2/BrCl (Calvert and Lindberg, 2004). Recent work in sub-Arctic Canada has further raised the importance of halocarbons in Arctic atmospheric chemistry. A combination of Differential Optical Absorption Spectroscopy (DOAS) observations of IO and measurements of atmospheric mixing ratios of halocarbons has revealed episodes of elevated IO, accompanied by a variety of iodocarbons (Mahajan et al., 2010). Air-mass back trajectories show that the iodine compounds originated from open water polynyas in the sea ice covered Hudson Bay. Using the one-dimensional Tropospheric Halogen Chemistry Model (THAMO) (Saiz-Lopez et al., 2008), Mahajan et al. (2010) reported large and significant decreases in ambient ClI) under 2 × ambient CO2 (46 ± 4 %) and 3 × ambient CO2 (131 ± 11 %) relative to ambient control mesocosms. By contrast, Hopkins et al. (2010) reported large and significant decreases in a variety of iodocarbons under high CO2 (~750 µatm) relative to present day control mesocosms (~380 µatm), whilst the bromocarbons showed little response to the future conditions. Now, we need to understand how the net production of halocarbons from other ocean regions may respond to OA. Furthermore, different species of phytoplankton are known to produce differing quantities of halocarbons. Therefore, in order to gain an understanding of the future flux of marine halocarbons to the atmosphere, a whole ecosystem approach must be adopted and mesocosm experiments provide this vital platform.

Previous mesocosm experiments performed in Norwegian temperate coastal waters have given contrasting effects of OA on halocarbons. Wingenter et al. (2007) observed large increases in chloriodomethane (CH2ClI) under 2 × ambient CO2 (46 ± 4 %) and 3 × ambient CO2 (131 ± 11 %) relative to ambient control mesocosms. By contrast, Hopkins et al. (2010) reported large and significant decreases in a variety of iodocarbons under high CO2 (~750 µatm) relative to present day control mesocosms (~380 µatm), whilst the bromocarbons showed little response to the future conditions. Now, we need to understand how the net production of halocarbons from other ocean regions may respond to OA. As marine halocarbons may be key players in Arctic atmospheric chemistry now and perhaps to a greater extent in the future, the aim of this study was to investigate how their net production and subsequent sea-to-air flux may be affected by future OA.

2 Materials and methods

2.1 General experimental set-up

A mesocosm experiment was performed between 31 May and 7 July 2010 in Kongsfjorden (78°56.2′N; 11°53.6′E), on the west coast of Spitsbergen, the largest island of the
Table 1. Mean $p$CO$_2$ (µatm) and pH (on the total scale) for the halocarbon sampling period ($t_4$–$t_{27}$) and for each phase of the experiment referred to in this article. See Bellerby et al. (2012) for full details of the evolution of the carbonate system within the mesocosms.

Svalbard Archipelago. A total of nine mesocosms were deployed in the fjord, moored in sets of three with ~40 m between each mesocosm and ~50 m between the triplets, and each capable of enclosing ~50 m$^3$ of seawater. The mesocosms were filled with fjord water which was screened through 3 mm mesh to eliminate larger organisms including pteropods. On 2 June ($t_{-5}$), the mesocosms were closed, allowing no further exchange with the surrounding fjord water. The mesocosms were fully open to the atmosphere, but were covered with a transparent protective lid to minimise external nutrient inputs from seabirds and rain. Seven of the mesocosms received varying amounts of CO$_2$-saturated seawater over a period of 5 days ($t_{-1}$ to $t_4$), resulting in a range of pCO$_2$ levels, from ~185 to 1420 µatm (Phase 0). The two control mesocosms received no CO$_2$ addition, and represented the in situ carbonate chemistry of the fjord (175–180 µatm). Once the pCO$_2$/pH levels had been adjusted, daily experimental sampling of the mesocosms for halocarbons began, beginning on 11 June ($t_4$) and continuing until 4 July ($t_{27}$). Table 1 gives a summary of the mean $p$CO$_2$ (µatm) and pH (on the total scale) for the period $t_4$–$t_{27}$, as well as mean values for the three experimental phases that are referred to in this paper. Nutrients were added to the mesocosms on 20 June ($t_{13}$) (mean concentrations: nitrate 5.56 µM, phosphate 0.39 µM, and silicate 1.47 µM). Full details of the experimental setup, evolution of the carbonate systems of the mesocosms and nutrient additions are given by Bellerby et al. (2012) and Schulz et al. (2013).

2.2 Sampling for halocarbon compounds

Samples for halocarbon analysis were taken using a depth integrating water sampler (IWS) (Hydrobios, Kiel, Germany) deployed from a small boat, suitable for the collection of trace gas-sensitive samples. The sampler was manually lowered through the water column to depth, and programmed to collect a 12 m-integrated sample. Once returned to the boat, a length of Tygon tubing was attached to the outlet at the bottom of the sampler and sub-samples for halocarbon analysis were collected in 250 mL amber glass-stoppered bottles. The bottle was rinsed three times before the Tygon tubing was placed to the bottom of the bottle, allowing it to gently fill and overflow three times. On the fourth filling, the bottle was filled to the top and the glass-stopper was replaced, ensuring the absence of bubbles or headspace. Samples were transported in a cool box back to the laboratory onshore, and all were analysed within 6 h of collection.

2.3 Quantification of halocarbon compounds

Seawater sub-samples were gently withdrawn from the amber glass-stoppered bottles using a 100 mL glass syringe and 1/8” nylon syringe extension. The sample was filtered through a 0.7 µm filter (GF/F, Whatman) into a second syringe, ensuring that the introduction of bubbles into the samples was avoided at all times. Following the addition of two deuterated surrogate analytes to monitor instrument sensitivity drift (Martino et al., 2005; Hughes et al., 2006), a 40 mL sample was injected into a glass purge vessel, and the halocarbons were extracted by purging the seawater with ultra-high purity (BIP) nitrogen for 10 min at a flow rate of 90 mL min$^{-1}$. Aerosols were removed from the purge gas stream using glass wool contained within a section of glass tubing, and a counterflow nafion drier using oxygen-free nitrogen at a flow rate of 90 mL min$^{-1}$. The sample was avoided at all times. Following the addition of two deuterated surrogate analytes to monitor instrument sensitivity drift (Martino et al., 2005; Hughes et al., 2006), a 40 mL sample was injected into a glass purge vessel, and the halocarbons were extracted by purging the seawater with ultra-high purity (BIP) nitrogen for 10 min at a flow rate of 90 mL min$^{-1}$. Aerosols were removed from the purge gas stream using glass wool contained within a section of glass tubing, and a counterflow nafion drier using oxygen-free nitrogen at a flow rate of 90 mL min$^{-1}$ was used to dry the gas. Halocarbons were trapped on triple-bed stainless steel solid sorbent tubes (Markes International Ltd.) containing Tenax, Carbograph and Carboxen, held at 1–2 °C in a custom-made peltier-cooled metal block. Sample tubes were analysed immediately after trapping using a semi-automated system.
consisting of an Agilent Gas Chromatograph-Mass Spectrometer (GC-MS), coupled to a Markes Unity thermal desorption (TD) platform. The GC was fitted with a 60 m DB-VRX capillary column (0.32 µm film thickness, J & W Ltd.), and the MS was operated in electron ionization (EI)/single ion mode (SIM) throughout the analyses. Within Unity, the sample tubes were heated to 200 °C for 5 min, and the desorbed sample was re-focused on a cold trap held at −10 °C. Following this, the cold trap underwent rapid heating up to 290 °C at a rate of 100 °C s−1 and the sample was introduced to the GC column using a He carrier flow rate of 2 mL min−1. The GC oven was held at 40 °C for 5 min, then heated to 200 °C at a rate of 20 °C min−1 and held for 2 min. Finally, the oven was heated to 240 °C at a rate of 20 °C min−1 and held for 4 min. The total run time was 21 min, and the MS collected data between 6 and 14 min of the run. Calibration and quantification of the compounds was performed using laboratory-prepared liquid standards, by dilution of the pure compounds into ultra-high purity methanol. The primary standards were prepared gravimetrically, the secondary standards were prepared gravimetrically, the secondary and working standards by serial dilution. The analytical error based on triplicate samples were: <5 % for Iodomethane (CH3I), 2-iodopropane (2-C3H7I), 1-iodopropane (1-C3H7I), chloroiiodomethane (CH2ClI), bromoiiodomethane (CH2BrI), <10 % for CH2I2, bromoform (CHBr3), dibromomethane (CH2Br2), dibromochloromethane (CHBr2Cl), and 10–15 % for Iodoethane (C2H5I), bromochloromethane (CH2BrCl). In order to prevent the possibility of contamination of natural samples with halocarbon standards, all working standards were stored at −20 °C in a separate laboratory to where analyses were carried out, and handling of standards was undertaken in a fume hood. Additionally, separate glassware was used for standard runs and sample runs. Instrumental and procedural blanks were performed daily before the commencement of sample analyses, and the system was invariably found to display no contamination.

2.4 Sea-to-air flux of halocarbons

The sea-to-air flux of halocarbons, determined by the concentration difference between the air and seawater after correcting for solubility, was estimated for all mesocosms. Gas exchange in the mesocosms was determined by the addition of 3 times-atmospheric concentrations of N2O and the measurement of the subsequent loss rates, allowing the transfer velocity (k) of N2O to be derived and enabling the estimation of the flux of other gases. For a detailed description of methods and results, see Czerny et al. (2013). Transfer velocities of halocarbons (khalo) were derived as follows:

\[ k_{\text{halo}} = k_{N20} / (S_{\text{halo}} / S_{N20})^{0.5}. \]  

The Schmidt number of halocarbons (S_{\text{halo}}) was estimated based on experimentally determined values of molecular diffusivity for CH3Br (De Bruyn and Saltzman, 1997), using an approach described by Moore and Groszko (1999). Estimated fluxes of halocarbons could then be calculated, using experimentally determined values of the dimensionless Henry’s Law Coefficient (Moore et al., 1995), and the only reported atmospheric concentrations of halocarbons from Ny-Ålesund reported by Schall and Heumann (1993) (mean 0.46 pptv, range < 0.08–1.02 pptv). Fluxes were low relative to open ocean measurements due to the sheltered nature of the mesocosm environment and a minimal wind speed component (Czerny et al., 2013).

2.5 Ancillary measurements

All ancillary measurements described here were taken directly from the integrated water sampler from the same cast used to collect the halocarbon samples, thus providing data that is directly comparable to halocarbon concentrations.

2.5.1 Chl a and additional phytoplankton pigments

Samples for both chl a and additional phytoplankton pigments were processed as soon as possible after sampling, and in the meantime, were stored at the in situ temperature of the fjord. For chl a 500 mL of seawater was filtered onto GF/F filters (Whatman), and immediately frozen and stored at −20 °C. Chl a was measured after a minimum of 24 h in the freezer, and extraction was performed with 10 mL acetone (90 %). The filter was homogenised for 4 min with 5mL acetone, after which an additional 5 mL was added and the sample centrifuged. The supernatant was then analysed fluorometrically after the method of Welschmeyer (1994). For determination of the individual phytoplankton pigments, 2 x 750 mL were filtered, which was reduced to 1 x 750 mL at the onset of the bloom. The filters were immediately frozen and stored at −80 °C until analysis at GEOMAR. Pigments were extracted with 3 mL acetone and analysed using high pressure liquid chromatography (HPLC), with the addition of Canthaxanthin as an internal standard.

2.5.2 Phytoplankton abundance and composition

Phytoplankton composition and abundance were determined by analysis of fresh samples on a Becton Dickinson FACSort flow cytometer (FCM) equipped with a 15 mW laser exciting at 488 nm and with a standard filter set up. Samples were analysed at high flow rate (~150 µL min−1), and specific phytoplankton groups were discriminated in bivariate scatter plots by differences in side scatter and red-orange fluorescence (Tarran et al., 2001).

2.5.3 Total bacteria abundance

Samples for bacterial enumeration were fixed for 30 min at 7 °C with glutaraldehyde (25 %, EM-grade) at a final concentration of 0.5 % before snap freezing in liquid nitrogen and storage at −80 °C until analysis. Bacteria were counted using an FCM according to Marie et al. (1999). Briefly, thawed
samples were diluted with Tris-EDTA buffer (10 mM Tris-HCl and 1 mM EDTA, pH 8) and stained with the green fluorescent nucleic acid-specific dye SYBR-Green I (Molecular Probes, Invitrogen Inc.) at a final concentration of $1 \times 10^{-4}$ of the commercial stock, in the dark at room temperature for 15 min. Bacteria were discriminated in bivariate scatter plots of green fluorescence versus side scatter.

2.6 Statistical analyses

In order to identify differences in halocarbon concentrations between mesocosms, one-way analyses of variance (ANOVA) were applied to the data. Initially, tests of normality were applied ($p < 0.05 = \text{not normal}$), and if data failed to fit the assumptions of the test, linearity transformations of the data were performed (logarithmic or square root), and the ANOVA proceeded from this point. The results of ANOVA are given as follows: $F =$ ratio of mean squares, $df =$ degrees of freedom, $\sigma =$ significance of $F$ test, $p =$ level of confidence. For those data which still failed to display normality following transformation, a rank-based Kruskal-Wallis test was applied ($H =$ test statistic, $df =$ degrees of freedom, $p =$ level of confidence).

Relationships between halocarbons and a range of other parameters were investigated using Pearson’s correlation coefficients ($R$), along with the associated probability ($F$ test, $p < 0.05 =$ significant). Net loss and production rates of halocarbons were derived from linear regression analyses of halocarbon concentration data as a function of time, to give the rate coefficient (pmol L$^{-1}$ d$^{-1}$), the coefficient of determination ($R^2$), the standard error (SE) of the rate and the associated level of confidence ($F$ test, $p < 0.05 =$ significant).

3 Results

3.1 Halocarbon temporal dynamics

Data for chlorophyll $a$ (chl $a$) and microbial plankton counts (nanoeukaryotes and picoeukaryotes, total bacteria) are shown in Fig. 1, and concentrations of halocarbons are shown in Fig. 2. The experiment was divided into three phases (PI, PII, PIII) based on the addition of nutrients and the dynamics of chl $a$ (Schulz et al., 2013). The divisions between phases are indicated on the figures as grey vertical lines (see Table 1 for a summary of timings). Mean concentrations of all halocarbons in the control mesocosms M3 and M7 were not significantly different from each other (Kruskal-Wallis ANOVA on ranks, $p > 0.05$ for all halocarbons).
3.1 Iodocarbons

Concentrations of CH3I and C2H5I (Fig. 2a and b) showed some variability over the course of the experiment, falling gradually during PI, in parallel to chl a concentrations and nanophytoplankton abundances. Peaks occurred following nutrient addition and in parallel with the chl a peak on t19 in PII, and during the rapid rise in chl a observed during PIII which was attributed to increases in diatoms, prasinophytes, and to a certain extent haptophytes (Schulz et al., 2013). Concentrations ranged from 0.04 to 10.29 pmol L$^{-1}$ and 0.06 to 3.32 pmol L$^{-1}$, for CH3I and C2H5I respectively. Concentrations of the propyl iodides (Fig. 2c) were less variable, with concentrations varying by less than 0.5 pmol L$^{-1}$, and overall mean concentrations of 0.21 pmol L$^{-1}$ (2-C3H7I) and 0.12 pmol L$^{-1}$ (1-C3H7I). However, concentrations did show some increase that coincided with the initial chl a maximum in PII. 2-C3H7I was consistently higher than 1-C3H7I by ~ 0.1 pmol L$^{-1}$. For all of the above and for the experiment as a whole, no significant differences in mean concentrations were detected between mesocosms and no apparent effect of pCO2 were observed (Kruskal-Wallis ANOVA on ranks (df = 8): CH3I H = 6.06, p = 0.64; C2H5I H = 15.03, p = 0.06; 2-C3H7I H = 11.73, p = 0.11; 1-C3H7I H = 10.22, p = 0.18).

In contrast to all other halocarbons, CH3I2 concentrations (Fig. 2d) gradually increased over the course of the experiment, from below detection limit (D.L. < 10 fmol L$^{-1}$) on t4, reaching 0.5–1.0 pmol L$^{-1}$ by t27. M1 displayed significantly higher concentrations over almost the entire duration of the experiment, with a maximum and seemingly anomalous value of 2.5 pmol L$^{-1}$ on t19 (ANOVA F = 2.52, df = 8, σ = 0.014, p < 0.05). In PII concentrations showed some response to pCO2 treatment, with significantly higher mean CH3I2 concentrations as a function of mean pCO2 ($R^2 = 0.451$, n = 9, p < 0.05). CH2ClI concentrations (Fig. 2e) were generally stable (0.5–1.0 pmol L$^{-1}$), with the exception of a small rise to a peak on t14, just prior to the nutrient-induced increase in chl a. Finally, concentrations of CH2ClI did not respond significantly to pCO2 treatment, although concentrations in M1 were significantly higher than M6, M7 and M8 (Kruskal-Wallis ANOVA on ranks H = 22.19, df = 8, p = 0.005, pairwise comparison with Dunn’s method – all p < 0.05).

3.1.2 Bromocarbons

The temporal development of concentrations of CHBr3, CH2Br2 and CHBr2Cl (Fig. 2f–h) showed a high degree of similarity, with a gradual rise from t6, a sharp drop at the start of PI followed by a period of recovery during the nutrient-induced chl a peak, and falling or unchanging concentrations during PII. For the entire experiment the concentrations of CHBr3 > CH2Br2 > CHBr2Cl with mean concentrations for all mesocosms of 72.8 pmol L$^{-1}$ 12.4 pmol L$^{-1}$ and 2.8 pmol L$^{-1}$, respectively. Similarly to CH3I2, concentrations of CHBr3, CH2Br2 and CHBr2Cl were almost consistently higher in M1 (significantly higher for CHBr3 Kruskal-Wallis ANOVA on ranks H = 27.258, df = 8, p < 0.001), although they followed similar temporal trends to the other mesocosms. Concentrations of CH2BrCl (Fig. 2i) were low (< 0.1 pmol L$^{-1}$) and stable, with the exception of a small number of anomalous data points in PI and PII. CH2BrI showed little variability as the experiment...
correlations were identified with both chl a opposite nature to I-monohalocarbons. Significant negative correlations (Fig. 3e–h), although the trends were consistently of an opposite nature to I-monohalocarbons. Significant positive correlations with picoeukaryotes and total bacteria (Fig. 3i and l), whilst picoeukaryotes showed a significant positive relationship (Fig. 3j).

3.2 Halocarbons and biological parameters

In order to identify possible sources or sinks in the mesocosms, mean concentrations of halocarbons were compared with a number of biological parameters (chl a, nanoeukaryote and picoeukaryote abundance, and total bacteria abundance). To simplify these analyses and to give an overview of general trends, halocarbons concentrations were averaged across all mesocosms and assigned to three groups based on their common biological production pathways (Manley, 2002): (1) I-monohalocarbons (CH3I, C2H5I, 2-C3H7I, 1-C3H7I), potentially formed via methyl transferase activity, (2) I-polyhalocarbons (CH2I2, CH2ClI, potentially formed via iodoperoxidase activity, (3) Br-polyhalocarbons (CHBr3, CH2Br2, CH2BrCl, CHBrClI, CH2BrI), potentially formed via bromoperoxidase activity (compare Fig. 3). I-monohalocarbons showed the strongest correlations with biological parameters during PI (Fig. 3a–d). Significant positive correlations were identified with both chl a and nanophytoplankton (Fig. 3a and c), whilst significant negative correlations were observed with picoeukaryotes and total bacteria (Fig. 3b and d). No significant correlations were observed during PI and PII. PI also revealed a number of strong relationships between I-polyhalocarbons and biological parameters (Fig. 3e–h), although the trends were consistently of an opposite nature to I-monohalocarbons. Significant negative correlations were identified with both chl a concentrations and nanoeukaryote abundance (Fig. 3e and g), and significant positive correlations with picoeukaryotes and total bacteria (Fig. 3f and h). No significant correlations were seen in PII. In PIII, significant positive correlations were found with chl a and total bacteria, and significant negative correlations were found with picoeukaryotes. No significant correlations were identified for Br-polyhalocarbons during PI and PII (Fig. 3i–l). During PIII, chl a and total bacteria gave significant negative correlations (Fig. 3i and l), whilst picoeukaryotes showed a significant positive relationship (Fig. 3j).

3.3 Halocarbons and pCO2

In order to determine the effect of pCO2 on concentrations of halocarbons, the strength of the correlation between mean concentrations and pCO2 for each experimental phase was examined. A significant increase in both mean and cumulative concentrations of CH3I under increasing CO2 was seen in PIII (R = 0.67, F = 5.75, p < 0.05) (Fig. 4a). No further relationships were identified between the standing stocks of halocarbons and pCO2.

4 Discussion

Absolute concentrations of halocarbons measured in the mesocosms were comparable to two earlier studies that reported halocarbons from Kongsfjorden, and the data is summarised in Table 2 (Hughes, 2004; Schall and Heumann, 1993). Schall and Heumann (1993) (hereafter SH93) analysed seawater samples collected 1 km from the shore during September – a comparable location to the mesocosms, during a similar season. Mean concentrations of CH3I show strong similarity, although a greater range was observed in the mesocosms, perhaps a result of the nutrient-induced phytoplankton growth. Concentrations of the remaining compounds were generally lower in the mesocosms than those measured by SH93. Similarly, mean concentrations were consistently higher in the fjord compared to the mesocosms.
during this study, with the greatest difference in mean concentrations seen for CH$_2$I$_2$ (78 %) and the least difference for CH$_2$BrCl (28 %). Whilst differences in halocarbon concentrations between the fjord and mesocosms may be a product of the temporal progression of their respective microbial communities, variations in light regimes and exclusion of benthic processes may have contributed to the variations. For instance, almost minimal ultraviolet (UV) light (< 380 nm) was transmitted through the mesocosm foil (Matthias Fischer, personal communication, 2012), and furthermore, potential macroalgal sources of halocarbons were excluded from the mesocosms.

For a number of halocarbons, anomalous spikes in concentrations were observed on a small number of occasions (Fig. 2). Excluding the likelihood of contamination of the analytical system (see Sect. 2.3), it is possible that these elevated concentrations were caused by aggregates of biogenic material, known to be “hotspots” of halocarbon production, incidentally included in particular samples (Hughes et al., 2008).

4.1 Processes controlling halocarbon concentrations in the mesocosms

During this experiment, 11 individual halocarbon compounds were quantified, along with numerous other biological and chemical parameters. Attempts to discuss each halocarbon individually would lead to an extensive and complicated discussion. Therefore in order to rationalise the following section, the discussion will focus on one halocarbon from each of the groups detailed in Sect. 3.2, on the assumption that the remaining halocarbons of each group are subject to similar production and removal mechanisms: (1) CH$_3$I (I-monohalogenated), (2) CH$_2$I$_2$ (I-polyhalogenated) and (3) CHBr$_3$ (Br-polyhalogenated). These halocarbons are either the dominant gas from each group in terms of
concentrations and/or are the most important in terms of their influence on atmospheric chemistry.

4.1.1 Iodomethane (CH$_3$I)

The temporal dynamics of CH$_3$I were characterised by periods of both net loss and net production, resulting in concentrations that ranged between below D.L. ($< 1$ pmol L$^{-1}$) and $\sim 10$ pmol L$^{-1}$, suggesting active turnover of this compound within the mesocosms (Fig. 2a). Numerous strong relationships to biological parameters were identified, predominantly during PI (Table 3). CH$_3$I concentrations gave significant positive correlations with chl $a$, nanoeukaryotes, and phytoplankton pigment concentrations (fucoxanthin, chl C1/C2, peridinin), whilst CH$_3$I was inversely correlated with picoeukaryotes and total bacterial abundances. Yet, despite the apparent close association with biological activity and the strong CO$_2$ effect on a number of biological parameters (Brussaard et al., 2013; Schulz et al., 2013), no consistent or prolonged response to pCO$_2$ was seen in the concentrations of CH$_3$I.

In order to speculate on the lack of response of CH$_3$I concentrations to CO$_2$, the processes controlling the production and removal of CH$_3$I in seawater must first be explained. Direct biological production is thought to occur via methyl transferase enzyme activity by both phytoplankton and bacteria (Amachi et al., 2001). The strong correlations with a number of biological parameters in the mesocosms provide evidence for this source. In addition, production is possible from the breakdown of higher molecular weight iodine-containing organic matter (Fenical, 1982) and through photochemical reactions between organic matter and light (Richter and Wallace, 2004), both of which may have made some contribution to the production of CH$_3$I in the mesocosm. In terms of removal, CH$_3$I undergoes nucleophilic substitution and hydrolysis in seawater (Elliott and Rowland, 1993), although the rates of reaction are minimal at the water temperatures experienced during the experiment (0.1–0.3 % d$^{-1}$) so it is likely that these processes made a negligible contribution to the overall loss of CH$_3$I. It is also probable that some CH$_3$I undergoes consumption by bacteria, and results of laboratory incubations with $^{13}$C-labelled CH$_3$I have provided evidence of significant “biological” loss rates (Frances Hopkins, personal communication, 2012). Seawater CH$_3$I is also lost via the sea-to-air flux, and this comprised a relatively small component of the total loss during this experiment. For example, during PI the mean sea-to-air flux of CH$_3$I was estimated at 73.1 pmol m$^{-2}$ d$^{-1}$. Therefore, when scaled to allow comparison with the total net loss, assuming a 12 m deep mixed water column, this flux represents 8 fmol L$^{-1}$ d$^{-1}$, equivalent to $< 4$ % of the total (0.25 pmol L$^{-1}$ d$^{-1}$).

Clearly, the controls on seawater concentrations of CH$_3$I are varied and complex. Furthermore, halocarbons occur at such low levels in seawater (picomolar) that distinguishing the underlying processes from bulk measurements is very difficult. The strongest relationships between CH$_3$I and biological activity were seen during PI, a period when the biological response to pCO$_2$ was minimal (Schulz et al., 2013). Over the course of PII and PIII, the coupling between CH$_3$I concentrations and biological parameters such as chl $a$ lessened, suggesting a decrease in the importance of direct biological production and a rise in the importance of other production processes. Consequently, a CO$_2$ effect on CH$_3$I of the kind seen on biological parameters during PII and PIII was not detectable.

4.1.2 Diiodomethane (CH$_2$I$_2$)

The main loss pathway for CH$_2$I$_2$ in seawater is photolysis at near-ultraviolet (UV) wavelengths (300–350 nm) (Martino et al., 2006). However, it is likely that this process was negligible in the mesocosms due to lack of UV transmission through the foil (Matthias Fischer, personal communication, 2012). The lack of photolysis may have facilitated the gradual increase in CH$_2$I$_2$ concentrations over the course of the experiment (Fig. 2d). Furthermore, CH$_2$I$_2$ was the only halocarbon to show a significant positive response to pCO$_2$ chiefly during PIII (Fig. 4a). The temporal data underwent linear regression analysis to reveal significant net production rates (pmol L$^{-1}$ d$^{-1}$) in all mesocosms (Table 4). Rates ranged from 0.027 pmol L$^{-1}$ d$^{-1}$ in M3 to 0.039 pmol L$^{-1}$ d$^{-1}$ in M9. Next, net production rates

Leblanc et al., 2006). The exact reason for algal-mediated production of volatile halocarbons is not fully understood, although theories exist as to the function of this process (Manley, 2002; Leblanc et al., 2006). As the consequence of haloperoxidase activity is to reduce H2O2 concentrations, it provides an antioxidant function. Therefore the up-regulation of CH2I2 production seen here in response to altered seawater carbonate chemistry, or indeed some other unidentified stressor, may be indicative of an adaptive response due to perturbed cell physiology amongst the plankton community.

The strong significant negative correlations between CH2I2 and total bacterial abundances over the duration of the experiment are intriguing and suggest some bacterial involvement in the turnover of this compound. There are no reported studies of the biological consumption of CH2I2. However, there is direct evidence for bacterial consumption of CH2Br2 (Goodwin et al., 1997, 1998), so this process cannot be ruled out for CH2I2. A small number of studies have investigated the involvement of bacteria in the production of I-polyhalocarbons, yielding somewhat limited and speculative information. Strains of iodine-oxidising bacteria (IOB) have been isolated from seawater, implicating species closely related to the marine bacterium Roseovarius tolerans (aerobic bacteriochlorophyll a-producer) (Fuse et al., 2003; Amachi, 2008). During laboratory enrichment incubations, IOB directly produced free iodine (I2) which led to the production of abundant organic iodine species, specifically CH2I2, CH2ClI and CHI3 via an extracellular oxidase enzyme. Although enrichment incubations are far removed from processes occurring in natural seawater, Amachi (2008) speculates that IOB may be widely distributed in the marine environment, raising the possibility that given the right conditions, IOB could significantly contribute to the production of CH2I2 in the marine environment. The significant negative correlations between bacterial abundance and CH2I2 concentration as well as increasing ratios of CH2I2 per bacteria cell with increasing pCO2 suggest either: (1) an increase in bacterial production of CH2I2, or (2) a decrease in bacterial consumption of CH2I2, in response to increasing pCO2.

for each mesocosm underwent correlatively analysis with the associated mean pCO2, revealing significant positive correlations for both the whole experiment (dashed line symbols, $R = 0.79$, $p < 0.05$) and for PIII (solid line, $R = 0.72$, $p < 0.05$) (Fig. 4b).

Furthermore, concentrations of CH2I2 were strongly, and often significantly, correlated with a number of biological parameters. Shown in Table 5, CH2I2 was closely positively correlated with both chl a and total bacteria for the whole experiment, whilst close positive relationships with the phytoplankton pigments fucoxanthin and peridinin were observed during PIII. Taking into account the relationship between CH2I2 and biological parameters, the possible reasons for an increase in net production of CH2I2 in response to increasing pCO2 will be explored in the following section.

The production of I-polyhalocarbons (CH2I2, CH2ClI) can be the result of iodoperoxidase enzyme activity that catalyses the destruction of H2O2 and stimulates iodination reactions to form polyhalogenated products (Moore et al., 1996; Leblanc et al., 2006). The exact reason for algal-mediated production of volatile halocarbons is not fully understood, although theories exist as to the function of this process (Manley, 2002; Leblanc et al., 2006). As the consequence of haloperoxidase activity is to reduce H2O2 concentrations, it provides an antioxidant function. Therefore the up-regulation of CH2I2 production seen here in response to altered seawater carbonate chemistry, or indeed some other unidentified stressor, may be indicative of an adaptive response due to perturbed cell physiology amongst the plankton community.

Due to its high reactivity and short photolytic lifetime, CH$_2$I$_2$ is potentially one of the most important sources of iodine atoms to the coastal marine boundary layer (Carpenter et al., 1999). Thus, changes to the sea-to-air flux of this compound could have implications for the catalytic destruction of tropospheric ozone (Chameides and Davis, 1980) and for new particle formation (O’Dowd et al., 2002). Mean fluxes ranged from −0.02 (M6) to 4.1 pmol m$^{-2}$ d$^{-1}$ (M4) during PI (overall mean 1.06 pmol m$^{-2}$ d$^{-1}$), and 7.1 (M6) to 34.4 pmol m$^{-2}$ d$^{-1}$ (M1) in PII (overall mean 12.3 pmol m$^{-2}$ d$^{-1}$). During PIII, an increase in flux was seen in all mesocosms, with an overall mean of 30.3 pmol m$^{-2}$ d$^{-1}$, and a range of 24.8 (M7) to 37.3 (M9) pmol m$^{-2}$ d$^{-1}$. There are a number of weaknesses in the calculation of the flux – not least the atmospheric values (Schall and Heumann, 1993), so conclusions should be drawn with caution. In PI and PII, no significant differences in flux were detected between mesocosms. Figure 4c shows the estimated mean cumulative fluxes for PIII plotted as a function of pCO$_2$, showing a significant relationship ($p = 0.04$) with increasing pCO$_2$.

4.1.3 Bromoform (CHBr$_3$)

CHBr$_3$ is the most abundant form of volatile organic bromine in seawater (Carpenter and Liss, 2000; Quack et al., 2007; Hughes et al., 2009), and predictably dominated the concentrations of bromocarbons in the mesocosms (Fig. 2f–2j). No relationship between CHBr$_3$ concentrations and pCO$_2$ treatment was observed, and there was a high degree of similarity in concentrations in the majority of mesocosms.

A key feature of the CHBr$_3$ data were the consistently higher concentrations observed in M1, most apparent from t$_{12}$ to t$_{19}$, and from t$_{20}$ to t$_{27}$ (Fig. 2f). The elevated concentrations occurred immediately after a period of rapid net production in all mesocosms. Significant net production rates were detected in M1 for the periods t$_{10}$–t$_{13}$ (22.3 ± 4.1 pmol d$^{-1}$, $p = 0.03$) and t$_{19}$–t$_{21}$ (33.0 ± 1.9 pmol d$^{-1}$, $p = 0.04$), significantly higher than the net production rates of the remaining mesocosms. These periods of net production were immediately followed by net loss over t$_{13}$–t$_{16}$, and t$_{21}$–t$_{27}$ in all mesocosms, during which M1 displayed the greatest rates of net loss (12.6 ± 1.8 pmol d$^{-1}$, $p = 0.02$ and 8.0 ± 1.0 pmol d$^{-1}$, $p = 0.001$, respectively). This suggests enhanced production and turnover of CHBr$_3$ in M1 relative to the other mesocosms.

During the final phase of the experiment significant net loss rates were observed in all mesocosms, ranging from the maximum in M1 (see above) to a minimum of 2.9 ± 0.3 pmol d$^{-1}$ in M8 over t$_{21}$–t$_{27}$ (Table 6). There was found to be no relationship between the net loss rates and pCO$_2$ for this period of the experiment (Fig. 5a). This period of net loss coincided with strong negative correlations between CHBr$_3$ and total bacteria, with correlation coefficients (R) ranging from 0.78 to 0.98 (Table 6). Excluding the possibility of an effect of pCO$_2$, the potential mechanisms responsible for the differences in net production and loss of CHBr$_3$ between the mesocosms were investigated further. In seawater, a number of processes act as sinks for CHBr$_3$ including (i) hydrolysis, (ii) reductive dehalogenation, (iii) halogen substitution, and (iv) photolysis. With half-lives at Arctic seawater temperatures of 680–1000 yr and 74 yr respectively,
(i) and (iii) are of little importance in this discussion (Quack and Wallace, 2003). Reductive dehalogenation (ii) can occur in anaerobic conditions so is also not relevant to the mesocosms (Quack and Wallace, 2003; Vogel et al., 1987). Microbial degradation has not been directly observed (Goodwin et al., 1997), although there is some evidence that it may occur at reasonable rates within the water column of both polar and tropical waters (Hughes et al., 2009; Quack et al., 2007). Photolysis is considered to be the largest internal sink for CHBr3 (Carpenter and Liss, 2000); however this constitutes only ∼2% of the sea-to-air flux. The mean estimated flux of CHBr3 for all mesocosms, when scaled as described for CH3I, was 0.30 pmol L⁻¹ d⁻¹ (min. 0.26 pmol L⁻¹ d⁻¹ (M8), max. 0.36 pmol L⁻¹ d⁻¹ (M1)), with little difference between mesocosms, and no effect of pCO2. Therefore, these estimated fluxes can explain between 5% and 12% of the net loss.

Using this information, it is possible to speculate on the dominant processes controlling the concentration of CHBr3 in the mesocosms. A key feature of the CHBr3 data was a strong and significant relationship between the observed net loss rates (corrected for the sea-to-air flux) over t21–t27 and the seawater concentrations of CHBr3 on t21 (Fig. 5b). This apparent concentration-dependence of loss rates may indicate that the turnover of CHBr3 in the mesocosms is related to biological processes, with the linear relationship representing the biological uptake rate kinetics. This is supported by the observed significant relationships between CHBr3 concentrations and total bacteria abundances (Table 6). However, this process is apparently not sensitive to the altered pCO2 conditions.

4.2 Comparison to a previous mesocosm experiment

Concentrations of a variety of halocarbons from a CO2 enrichment experiment performed in temperate, coastal waters off Bergen, Norway in 2006 were reported by Hopkins et al. (2010). During the 2006 experiment, maximum chl a concentrations of 6–11 µg L⁻¹ were more than double of those measured in this study, and the plankton community showed a strong response to CO2, with significant decreases in chl a and microbial plankton under high CO2. Nevertheless, both the concentrations and the general response of the bromocarbons to biological activity and pCO2 showed some similarity to the present study conducted in Arctic waters. In contrast, concentrations of iodocarbons were markedly higher during the 2006 experiment, particularly for CH2I2 and CH2I2I with maximum concentrations of ∼700 and ∼600 pmol L⁻¹, respectively. Furthermore, large, and in some cases significant, reductions in concentrations of all iodocarbons occurred at higher pCO2 (CH3I: −44 %, C2H5I: −35 %, CH2I2: −27 %, CH2I2I: −24 %). The temporal dynamics of the iodocarbons suggested a close association with the plankton communities. The lower biomass and relatively lower biological activity observed in this Arctic experiment may have suppressed a clear response in the iodocarbon concentrations to increasing CO2 of the kind seen in the 2006 experiment.

5 Conclusions

Concentrations of a range of halocarbons were measured during a 5-week CO2-perturbation mesocosm experiment in Kongsfjorden, Spitsbergen, during June and July 2010. The temporal standing stocks of the majority of halocarbons did not significantly respond to pCO2 over a range from ∼175 µatm to ∼1085 µatm. Halocarbon concentrations did
show a large number of significant correlations with a range of biological parameters, suggesting some influence of the biological communities on the production and consumption of these trace gases in Arctic waters. The temporal dynamics of CH$_3$I, combined with strong correlations with biological parameters, indicated a biological control on concentrations of this gas. However, despite a CO$_2$ effect on various components of the community, no effect of pCO$_2$ was seen on CH$_3$I. CH$_2$I$_2$ concentrations were closely related to chl $a$ and total bacteria over the whole experiment and with the phytoplankton pigments fucoxanthin and peridinin during PIII, strongly suggesting biological production of this gas. Both the concentrations and the net production of CH$_2$I$_2$ showed some sensitivity to pCO$_2$, with a significant increase in net production rate and sea-to-air flux at higher pCO$_2$, particularly during the later stages of the experiment. The temporal dynamics of CHBr$_3$ indicated rapid turnover of this gas, and concentrations varied between mesocosms, although not explainable by pCO$_2$ treatment. Instead, net loss rates (corrected for loss via gas exchange) displayed a degree of concentration-dependence, and strong negative correlations with bacteria during periods of net loss suggest a degree of bacterial consumption of CHBr$_3$ in Arctic waters. The results of the first Arctic OA mesocosm experiment provide invaluable information on the production and cycling of halocarbons in Arctic waters, demonstrating strong associations with the biological communities. Although the effects of OA on halocarbons concentrations were in general subtle, some significant affects were observed. The role of halocarbons in Arctic atmospheric chemistry may increase in importance in the coming decades due to increases in open water with the Arctic atmospheric chemistry may increase in importance in the context of simulated Arctic ocean acidification, Biogeosciences Discuss., 9, 15541–15565, doi:10.5194/bg-9-15541-2012, 2012.

Acknowledgements. This work is a contribution to the European Project on OCean Acidification (EPOCA) which received funding from the European Community’s Seventh Framework Programme (FP7/2007–2013) under grant agreement no. 211384. We gratefully acknowledge the logistical support of Greenpeace International for its assistance with the transport of the mesocosm facility from Kiel to Ny-Ålesund and back to Kiel. We also thank the captains and crews of M/V ESPERANZA of Greenpeace and R/V Viking Explorer of the University Centre in Svalbard (UNIS) for assistance during mesocosm transport and during deployment and recovery in Kongsfjorden. We thank Signe Koch Klavsen for providing phytoplankton pigment data and Matthias Fischer for UV measurements through the mesocosm foil. We are grateful to the UK Natural Environmental Research Council for the accommodation and support provided through the NERC-BAS station in Ny-Ålesund. We also thank the staff of the French–German Arctic Research Base at Ny-Ålesund, in particular Marcus Schuhmacher, for on-site logistical support. Financial support was provided through the European Centre for Arctic Environmental Research (ARCFAC) (grant number ARCFAC026129-2009-140) and through Transnational Access funds by the EU project MESOQUA under grant agreement no. 22822. Finally, we would like to thank Ulf Riebesell, Sebastian Krug and the whole of the Svalbard mesocosm team, who showed great team spirit and comradeship and helped to make the experiment both enjoyable and successful.
