THE COMBINATION OF AUTOFLUORESCENCE ENDOSCOPY AND MOLECULAR BIOMARKERS IS A NOVEL DIAGNOSTIC TOOL FOR DYSPLASIA IN BARRETT’S OESOPHAGUS
ABSTRACT

OBJECTIVE: Endoscopic surveillance for Barrett’s oesophagus (BO) has major limitations including multiple biopsies, sampling error and subjectivity of pathological diagnosis of dysplasia. We aimed to compare a biomarker panel on minimal biopsies directed by autofluorescence imaging (AFI) with the standard surveillance protocol for the diagnosis of prevalent dysplasia.

DESIGN: We performed a cross-sectional prospective study on 175 patients with BO in three tertiary referral centers. All patients underwent high resolution endoscopy followed by AFI and 157 completed the biopsy protocol. Aneuploidy/tetraploidy; 9p and 17p loss of heterozygosity; RUNX3, HPP1 and p16 methylation; p53 and cyclin A immunohistochemistry (IHC) were assessed on biopsies targeted by AFI. Bootstrap resampling was used to select the best diagnostic biomarker panel for high grade dysplasia (HGD) and early cancer (EC). This panel was validated in an independent cohort of 39 patients.

RESULTS: Aneuploidy, p53 IHC and cyclin A had the strongest association with dysplasia in the per-biopsy analysis and, as a panel, had an area under the receiver operating characteristic curve of 0.97 (95%CI 0.95-0.99) for the diagnosis of HGD/EC. The diagnostic accuracy for HGD/EC of the 3-biomarker panel from AFI+ areas was superior to AFI- areas (p<0.001). Furthermore, compared to the standard protocol this 3-biomarker panel had equal sensitivity for HGD/EC, with a 4.5-fold reduction in the number of biopsies. In an independent cohort of patients, the panel had sensitivity and specificity for HGD/EC of 100% and 90% respectively.

CONCLUSIONS: A 3-biomarker panel on a small number of AFI-targeted biopsies provides an accurate and objective diagnosis of dysplasia in BO.
INTRODUCTION

The incidence of oesophageal adenocarcinoma (OAC) has dramatically increased over the last 40 years in the Western world, while survival rates remain dismal. (1-3) Barrett’s oesophagus (BO) is the only recognized precursor to OAC and progresses to invasive cancer through low grade dysplasia (LGD), high grade dysplasia (HGD) and early intramucosal cancer (EC). (4) Despite the contradictory evidence on the benefit of endoscopic surveillance, (5, 6) all specialist societies recommend surveillance with protocol entailing four-quadrant random biopsies every two centimeters plus targeted biopsies of visible lesions (Seattle protocol). (7, 8) Diagnosis of HGD or EC leads to treatment recommendations generally involving endoscopic therapy to prevent development of advanced disease. (9) However, endoscopic surveillance has major limitations. The Seattle protocol is time consuming and invasive with subsequent poor adherence by endoscopists. (10, 11) In addition, dysplasia and EC can be inconspicuous leading to sampling error by random biopsies. (12) Hence, clinical justification and cost-effectiveness of endoscopic surveillance has been questioned, especially following recent evidence that the cancer risk in BO may be lower than previously thought. (13, 14)

To improve recognition of inconspicuous dysplasia, autofluorescence imaging (AFI) has been investigated. (15-17) AFI utilizes short wave-lengths of light to excite certain endogenous molecules (fluorophores) in the (GI) mucosa to emit a fluorescent signal. Dysplasia and EC can be associated with loss of autofluorescence, due to distortion of tissue architecture and molecular changes. (17) Two previous cross-over studies have shown that, although AFI can improve detection of inconspicuous dysplasia, it suffers from a high false positive rate (>60%) and its accuracy was not sufficient to replace the Seattle protocol. (15, 16) The nature of AFI false positivity is still unclear. We hypothesized that the AFI positivity may correlate with molecular abnormalities of the glandular tissue, not yet manifest as histological dysplasia.

An additional limitation of endoscopic surveillance is the significant inter-observer variability in the histopathological diagnosis of dysplasia, even among expert pathologists. (18, 19) To improve the objectivity of disease stage assessment, researchers have investigated molecular biomarkers. Some of these, such as over-expression of p53 (20-22) and cyclin A, (23) methylation of specific genes, (24) loss of heterozygosity (LOH) at the 17p and 9p loci and DNA ploidy abnormalities (25) associate with dysplasia. However, with the exception of p53 expression, these biomarkers have only been tested by single groups in single, retrospective cohorts of patients and this has hampered their translation into clinical practice. In addition, there is a lack of prospective studies testing multiple biomarkers in the same prospective cohort in order to identify the smallest, clinically applicable panel with the highest diagnostic accuracy. A further problem is that biomarkers performed on random biopsies are potentially subject to sampling error, due to the non-uniform distribution of molecular changes in BO. (25, 26) This limitation could be overcome using advanced imaging modalities to help target biopsies for biomarkers. We assessed the feasibility of this novel, combined approach in a recent retrospective pilot study. (27)

We thus hypothesised that combining AFI with molecular biomarkers could provide a synergistic approach to elucidating the overall dysplasia status of the patient and overcome limitations of conventional histology performed on random biopsies. Therefore, the primary aim of this
prospective study was to compare the accuracy of a panel of molecular biomarkers on AFI-directed biopsies with the Seattle protocol for the diagnosis of HGD/EC in BO. The secondary aims were: (1) assessment of diagnostic accuracy for the biomarkers for any grade of dysplasia; (2) validation of a large panel of biomarkers in an independent prospective study by an independent laboratory.

METHODS

Patients and setting

The study was approved by the Cambridgeshire 2 Research Ethics Committee (09/H0308/118). For the generation of the biomarker panel, a training cohort of 175 patients was recruited prospectively between April 2009 and October 2011 from three centers (Amsterdam, Cambridge, and Nottingham). For the validation of the panel an independent cohort of 39 patients was prospectively recruited at a single institution (Cambridge) between March 2012 and April 2013. Inclusion criteria were: age >18 years, known BE with minimum length of C≥2, M≥2 or C<2, M≥4 according to the Prague classification, referral for evaluation of dysplastic BE or follow-up post endoscopic resection for HGD/EC. Short segments of <2cm were excluded due to the excess of AFI-false positivity at the gastro-oesophageal junction (GOJ) and since sampling error is not such an issue for these cases. Exclusion criteria were: oesophagitis (Los Angeles grade ≥B); previous upper GI surgery (with exception of Nissen fundoplication) or known upper-GI tract abnormality (e.g. pharyngeal pouch); coagulopathy or anticoagulant/antiplatelet therapy for high risk conditions; active or severe cardiopulmonary disease or liver disease; dysphagia; special communication needs.

Endoscopic procedure

After written informed consent, patients were endoscoped with FQ260Z endoscopes (Olympus inc., Tokyo, Japan) as previously described. Four endoscopists performed the study procedures, but in order to uniform the interpretation of the AFI signal, the two endoscopists with less experience in AFI had to perform at least 30 AFI procedures prior to the study under supervision of endoscopists with extensive prior experience in AFI (JJGHMB and KR). The oesophagus was inspected first with a white light high resolution endoscope (HRE) to record the presence of any macroscopically visible lesions (Supplementary Figure 1A). Then, using the AFI mode, AFI positive (AFI+) areas (violet-purple in color) were carefully mapped. A representative AFI negative (AFI-) area (green color) was then selected as a negative control (Supplementary Figure 1B). In patients who had diffuse patchy AFI positivity throughout the BO (n=8) an AFI- control area could not be selected, but they were included in the per-biopsy (Figure 2) and final per-patient analysis (figure 4).

Biopsy and histology

Each AFI+ area and one AFI- area were biopsied for biomarker analysis and histopathology (Supplementary Figure 1A). All AFI+ areas within the tubular oesophagus, up to a maximum of four, were included in the research biopsy protocol, however small AFI+ areas (<1cm) within 1
cm from the gastro-oesophageal junction were excluded, due to the well known false positivity in close proximity to the gastric folds (30). Where possible (depending on the size of the AFI+ area), a maximum of three biopsies were taken in the following order of priority: one biopsy in formalin, one snap frozen biopsy in 10% dimethylsulfoxide (DMSO), one biopsy snap frozen dry. For AFI+ positive areas larger than 1 cm two or more biopsies were taken for histology to minimize sampling error, whereas AFI+ with a complex shape were considered as multiple AFI+ areas (Supplementary Figure 1B). Histopathological assessment of each AFI-targeted area relied on biopsies stored in formalin. Random biopsies were then taken according to the Seattle protocol. The histology was assessed by an expert GI pathologist at the respective participating center according to the Vienna classification. (31) All dysplastic cases, including indefinite for dysplasia (ID), were then reviewed by a second pathologist, with random pairing of the initial pathologist with one of the pathologists from the other two centres. Four pathologists took part to initial assessment, but only three participated to the reviewing process. In case of disagreement, consensus among three pathologists was reached through a review process, and this diagnosis was considered as the final histological outcome for the per-biopsy and per-patient analysis. Cases with ID without definite dysplasia after consensus review were regarded as non-dysplastic (NDBO). In accordance with the Vienna classification cases of HGD, carcinoma in situ and intramucosal adenocarcinoma were grouped together (HGD/EC), as they represent a common endpoint for endoscopic therapeutic intervention as per clinical guidelines (7) and expert consensus statements. (32) For the purpose of the biomarker analysis, all biopsies taken using the AFI mode were regarded as AFI-targeted (AFI+ and AFI-). With regards to the overall per-patient histopathological diagnosis, we considered diagnoses made using: a) the current clinical standard (Seattle protocol, i.e., biopsies on areas visible on HRE + quadrant random biopsies); b) the overall histology (a + histology on AFI-targeted biopsies).

**Biomarker analyses**

All molecular analyses were done at the Medical Research Council, Cancer Cell Unit (Cambridge, UK). The panel of molecular biomarkers analyzed in the training cohort (9-biomarker panel) comprised: aneuploidy, G2/tetraploidy, LOH at 9p and 17p loci, hypermethylation of p16, RUNX3, HPP1 and immunohistochemistry for p53 and cyclin A. Only the 3 biomarkers included in the final panel (aneuploidy and IHC for p53 and cyclin A) were performed in the validation cohort.

**Flow cytometry**

The snap frozen biopsies in DMSO were used for analysis of DNA content abnormalities and processed as described previously. (33) The isolated nuclei were analyzed by flow cytometry using a MoFlow (Beckman Coulter, Miami, FL, USA) or BD Influx™ (Becton, Dickenson biosciences, New Jersey, USA) by an expert cytometrist. The cell cycle histogram was analyzed using ModFit LT (Verity Software House, Topsham, ME, USA) by two investigators, who were blind to the histological outcome, and discordant results were reviewed jointly to reach agreement.
Quantitative methylation-specific PCR (Methylight)

DNA was extracted from snap frozen esophageal biopsies using the DNeasy® Blood & Tissue Kit (Qiagen, Hilden, Germany) according to the manufacturer’s instructions. DNA was bisulfite modified using an EpiTect® Bisulfite Kit (Qiagen) and the degree of methylation was analyzed by Methylight using a LightCycler® 480 (Roche diagnostics Ltd, Rotkreuz, Switzerland) with previously published Taqman primers and probes. (24) Normalized methylation values were calculated as previously described. (24)

Immunohistochemistry (IHC)

Staining was performed with the BOND™ System (Leica Microsystems, Ltd, Milton Keynes, UK) with an H1 antigen retrieval program. Antibodies used were: p53 clone DO7 (Dakocytomation, 1:50) and cyclin A (Novocastra, 1:40). The scoring was performed by a single author without prior knowledge of the clinical diagnosis. Surface cyclin A was scored as previously described, using a cut-off for positivity of 1% of positive surface cells. (23) P53 expression was scored positive when there were areas of strong staining or complete loss of staining, compared to the background levels, as previously described. (34)

Loss of heterozygosity (LOH)

LOH at 17p and 9p loci (p53 and p16 genes, respectively) was assessed on DNA extracted by phenol/chloroform. Microsatellite markers were used as previously published. (35) The microsatellite loci were amplified by multiplex PCR and the PCR products were combined with GeneScan™ LIZ® Size Standard and electrophoresed on an automated sequencing system (ABI 3130 xl Genetic Analyzer, Applied Biosystems, California, USA) according to the manufacturer’s protocol. GeneMapper® Software (Applied Biosystems) was used to analyse the peak height ratios of the alleles of a duodenal control and oesophageal biopsy and highlight LOH candidates. LOH was assessed on the basis of the following allelic imbalance ratios:

\[
\text{Allelic ratio of sample} = \frac{\text{Peak height of Allele 1}}{\text{Peak height of Allele 2}}
\]

\[
\text{Allelic Imbalance} = \frac{\text{Allele Ratio of Control Sample}}{\text{Allele Ratio of AFI Sample}}
\]

Ratio of > 1.35 or < 0.067 was considered as suggestive of LOH as instructed by the software. The sample was considered positive for LOH if >2 loci were suggestive for LOH for a particular gene.

Sample size and power

Previous data suggest that single biomarkers have a sensitivity for HGD/EC varying between 60 and 87%, however we assumed that, when combined into a panel, biomarkers could have 90%-95% sensitivity and 85-95% specificity. For a sensitivity of 90%, we calculated that to have an accuracy of 10% (95% CI: ±10%) we needed to recruit at least 35 patients with HGD/EC.
Statistics

For the purpose of the per-biopsy analysis, each AFI-targeted area was classified with: i. patient research number; ii. AFI status (AFI+ or AFI-); iii. binary outcome of the 9 biomarkers (positive or negative); iv. histological diagnosis (NDBO, LGD, HGD, EC). Chi-square tests were used to compare differences between groups. A p-value < 0.05 was considered statistically significant. We used $\kappa$-statistics to quantify interobserver agreement. For the reliability of pathological diagnosis, agreement among three expert pathologists for a diagnosis of any grade of dysplasia was calculated and expressed as weighted $\kappa$-value. For the reliability of endoscopic location and level of subjective suspicion for dysplasia of AFI targeted areas, the agreement was calculated and expressed as $\kappa$-value. In particular for the location of the AFI positive areas, agreement among endoscopists was defined as their specification of the epicenter of the AFI positive area within 30 degrees.

In some AFI-targeted areas some biomarkers were recorded as missing, due to the fact that some AFI+ areas were not large enough to permit the assessment of the full 9-biomarker panel, which relied on 3 biopsies. To ensure enough power and avoid the possibility that missing information biased the outcome of the analysis, missing data were imputed by multiple imputation (MI), as this method controls the influence of both randomly missing and non-randomly missing data. (36, 37) The imputation model included the 9 biomarkers and the histological diagnosis as variables. Five independent datasets were imputed and they were included in the analysis together with the original database, after removing samples containing missing values in variables of interest. To avoid inflating the diagnostic performance of biomarkers by applying the model to the same dataset from which it was developed (over-fitting), and prevent random selection of biomarker panels, bootstrap resampling was applied. In this analysis multiple rounds of a random selection of sub-samples were performed and the calculated accuracy of the parameter of interest validated in the remaining sub-sample. Details of the statistical methodology used for the generation and the validation of the biomarker panel are described in Supplementary material

All the analyses were performed using SPSS version 19.0 (SPSS Inc, Chicago, IL, USA) and R version 2.15.2.

RESULTS

Of the 175 participants recruited as part of the training cohort, 18 were excluded because of either a lack of biopsies for laboratory tests (n=4) or breach of biopsy protocol (e.g. biopsy mislabeling, no research biopsy in AFI+ areas taken, no random biopsies taken) (n=14). From the remaining 157 participants, we obtained 373 AFI-targeted biopsies (AFI+: AFI- = 230:143), which were processed for biomarkers and included in the per-biopsy analysis. The validation cohort consisted of 39 patients, from which 130 AFI-targeted biopsies were taken (AFI+:AFI- = 89:41). There were no significant differences between the two cohorts in the demographics and histologic outcomes as well as characteristics of AFI+ areas, however the validation cohort had a slightly higher number of AFI+ areas per patient (Table 1). The overall interobserver agreement among three expert pathologists for a diagnosis of any grade of dysplasia was
‘moderate’ (weighted $\kappa$-value 0.56, standard error 0.055). This is in keeping with previous studies comparing dysplasia rating between pathologists, underscoring the subjectivity of the diagnosis. With reference to the interpretation of the AFI status of selected areas for targeted biopsies, the agreement between observers was ‘good’ for the location of the area of interest ($\kappa$-value 0.68, standard error 0.104) and ‘moderate’ for the level of suspicion for dysplasia ($\kappa$-value 0.59, standard error 0.104).

**Association of biomarkers with dysplasia (per-biopsy analysis)**

We first sought to identify a small biomarker panel with the best diagnostic accuracy for prevalent dysplasia. To this end, we identified nine biomarkers that had the most robust correlation with dysplasia in BO based on published phase III and IV clinical studies. (20-25) Figure 1 shows the strategy used for the generation of the panel. The 9 biomarkers were tested in the AFI-targeted biopsies from the training cohort to assess their association with dysplasia on a per-biopsy basis. As shown in Table 2, all of the biomarkers associated with the presence of confirmed dysplasia (LGD, HGD or EC), with the exception of 9p LOH (p16). When restricting the analysis to the association between biomarkers and HGD/EC, we found similar results, in that only tetraploidy and 9p LOH lacked statistical significance.

Since large numbers of biomarkers are difficult to apply in the clinical setting, we used a strict statistical methodology to identify a small and clinically feasible biomarker panel. Since some AFI+ areas were not sufficiently large to allow three biopsies as per protocol, the dataset had 20% of missing values, which ranged between 13.4% and 28.5% for different biomarkers (Table 2). We used bootstrap resampling of the original database as well as on 5 imputed databases to

account for missing values. This statistical methodology has been previously developed to handle datasets with up to 50% of missing data in clinical studies. (38) We concentrated on the highest histological outcome for this analysis (HGD/EC), as this is what currently triggers therapeutic decisions according to clinical guidelines. We found that two IHC markers (p53 and cyclin A) and aneuploidy had the highest rate of inclusion in best bootstrap models in all the 5 imputed databases, as well as in the original database (Figure 2A) and for this reason they were selected to form a 3-biomarker panel. On a per-biopsy analysis this panel had AUCs of 0.93 (95% CI: 0.89-0.98) and 0.97 (95% CI: 0.95-0.99) for a diagnosis of any grade of dysplasia and HGD/EC, respectively (Figure 2B-C). These data showed that these 3 biomarkers have the strongest association with dysplasia and could be combined into a panel to aid clinical diagnosis.

Association between molecular biomarkers and AFI status
In order to translate the diagnostic accuracy for dysplasia of the biomarker panel from a single biopsy to a per-patient level, we determined that the biopsies should be targeted using an imaging tool rather than relying on...
a random biopsy. As discussed in the introduction we hypothesized that the AFI positive areas may be enriched for molecular abnormalities due to an abnormal genetic field effect. Hence, we then asked whether AFI positivity correlates with molecular abnormalities of the mucosa. We first analyzed the association between individual biomarker outcome and AFI status of the corresponding endoscopic area. Aneuploidy, 17p LOH, p53 IHC and cyclin A significantly associated with AFI positivity (p<0.05) (Supplementary Table 1). Since dysplasia is enriched in AFI positive areas and could represent a confounding factor, we looked at this association after exclusion of areas harboring dysplasia and found that aneuploidy and p53 IHC retained a significant association with AFI positivity (Supplementary Table 1). To confirm that this association translates into a clinical advantage, we looked at whether the 3-biomarker panel (aneuploidy, p53 IHC and cyclin A) had a better accuracy for an overall diagnosis of HGD/EC if assessed on AFI+ areas compared with AFI- areas. We performed this comparative analysis in 5 imputed databases as well as in the original database (Figure 3). To avoid over-fitting, we used the bootstrap samples as a training set and patients not selected in bootstrap sampling as a validation set. Notably, average AUCs in all 6 databases were significantly higher for the 3-biomarker panel assessed on AFI+ areas compared to AFI- areas. We therefore concluded that AFI positivity is associated with an enrichment of biomarkers and is a suitable tool to guide biopsies for analysis of biomarkers.
Internal validation of the 3-biomaker panel (per-patient analysis)

We sought to confirm that the biomarker panel selected in the per-biopsy analysis by the logistic regression model could correctly classify patients based on their highest grade of dysplasia assessed histologically. From a pool of 9 biomarkers, there are 84 different combinations of 3 biomarkers and 36 combinations of 2 biomarkers. We calculated the diagnostic accuracy of these 120 biomarker panels with different cut-offs of positive biomarkers in the 2000 bootstrap samples generated from the original database. Strikingly, the best diagnostic accuracy was achieved by the same panel identified in the per-biopsy analysis (p53 IHC, cyclin A IHC and aneuploidy), with a cut-off of 2 positive biomarkers to diagnose HGD/EC (Supplementary Table 2). We therefore took this combination of biomarkers forward as the final diagnostic panel to determine

Figure 2. A 3-biomaker panel including p53 IHC, cyclin A IHC and aneuploidy has high diagnostic accuracy for dysplasia. A. Inclusion frequencies of the nine biomarkers in 100 bootstrap samples for each MI database (n=5) and the original database (n=1). A stringent cut-off of 90 for the median over all 6 databases was used to select the best biomarkers. P53 IHC, cyclin A IHC and aneuploidy had median inclusion frequency above the threshold. B-C Area under the curve (AUC) for the diagnosis of any grade of dysplasia (B) and HGD/EC only (C) was calculated using the panel of biomarker selected in A.
histological outcome in the patients from the training cohort. Hence, we included patients with the 3-biomarker full dataset on AFI-targeted biopsies (n=112) (Figure 1B). In keeping with the results from bootstrap resampling, a cut-off of 2 biomarkers positive had the best accuracy (Supplementary Table 3). Using this cut-off to identify patients with high histological grade, only one patient with HGD was mis-classified with a low-risk biomarker signature (Figure 4 and Table 3). The biomarker panel had a sensitivity and a specificity of 95.8% (95%CI: 76.9%-99.8%) and 88.6% (95%CI: 79.7%-94.1%), respectively, for a diagnosis of HGD/EC, and 74.4% (95%CI: 57.6%-86.4%) and 94.5% (95%CI: 85.8%-98.2%), respectively, for a diagnosis of any grade of dysplasia. This translated into a similar diagnostic accuracy to the Seattle protocol, which also missed one patient with HGD/EC (Table 3). By comparison the Seattle protocol had a sensitivity of 95.8% (95%CI: 76.9%-99.8%) for a diagnosis of HGD/EC (p=1.0 when compared with 3-biomarker panel) and 84.6% (95%CI: 68.8%-93.6%) for a diagnosis of any grade of dysplasia (p=0.26). Relying on the histology of AFI+ areas, the sensitivity for HGD/EC was lower at 91.7%, although this difference was not statistically significant. Importantly, using this novel approach 2.8 biopsies per patient were taken on average compared with 12.8 for the standard biopsy protocol (p<0.001) (Table 3).

External validation of the 3-biomarker panel

We then tested the 3 biomarkers in an independent group of 39 patients. The panel had a sensitivity and a specificity of 100% and 90% (95%CI: 79.3%-100.0%), respectively, for a diagnosis
Table 3. Comparison among Seattle protocol, AFI-targeted histology and 3-biomarker panel on AFI+ areas. Seattle protocol includes all biopsies taken on HRE white light endoscopy (random + targeted on macroscopically visible abnormal areas). AFI+ histology includes biopsies taken on AFI+ areas, regardless of their appearance on white light. AFI + biomarkers column includes only the biopsies from AFI+ areas processed for the 3-biomarker panel.

Figure 4. Flow-chart of biomarker outcome in patient from the training cohort with full 3-biomaker dataset. Using a cut-off of 2 abnormal biomarkers to diagnose patients with prevalent HGD/EC, the 3-biomaker panel only missed one patient with HGD/EC. Ten patients with NDBO or LGD were classified as high risk for HGD/EC. The sensitivity and specificity of 3-biomaker panel for a diagnosis of HGD/EC were 95.8% (95%CI: 76.9%-99.8%) and 88.6% (95%CI: 79.7%-94.1%), respectively.

The sensitivity of the panel for HGD/EC was not significantly different from the Seattle protocol, which however missed one case of HGD. This current clinical standard protocol had a sensitivity of 88.9% for a diagnosis of HGD/EC (p=1.0 when compared with 3-biomarker panel) and 94.1% for a diagnosis of any grade of dysplasia (p=0.17), but relied on a significantly higher number of biopsies (p<0.001). We conclude that this 3-biomarker panel assessed on AFI-targeted biopsies has a similar sensitivity for HGD/EC compared to the Seattle protocol and allows a significant reduction in the number of biopsies required.
DISCUSSION

In the present study, we devised a novel strategy in which advanced endoscopic imaging can be used to direct biopsy sampling for biomarkers, which can provide a more objective read-out than dysplasia. Single biomarkers or panels of biomarkers have been shown to correlate with dysplasia in BO (21, 23, 24, 35) and in some cases to estimate the individual risk of progression. (23, 24, 35, 39, 40) This prospective multi-centre phase-4 study evaluated nine biomarkers with the most robust published data, and confirmed that eight of them were significantly associated with any grade of dysplasia and seven with HGD/EC. To our knowledge this is the first study that has validated such a large panel of biomarkers in a single prospective patient cohort. Furthermore, it is the first time that the previously published biomarkers have been validated in an independent laboratory. The rationale for using a biomarker panel stems from evidence that a combination of biomarkers performs better than single biomarkers on their own. (35) Clinical applicability of biomarkers relies on the feasibility of the specific laboratory assays, low enough costs and a manageable number of assays if combined into a panel. A stringent statistical methodology, which took into account missing data and assessed the strength of different combinations of biomarkers, indicated that p53 IHC, cyclin A IHC and aneuploidy constitute the panel with the best diagnostic accuracy for HGD/EC. This panel satisfies criteria for clinical applicability. P53 and cyclin A rely on IHC, which is a routine technique in pathology laboratories. Of these, p53 is currently already employed by some pathologists to aid in the diagnosis of dysplasia (20, 21) and has been recommended in the revised BSG guidelines. (41) For the evaluation of aneuploidy, we used a methodology based on flow cytometry analysis from frozen samples preserved in DMSO, as this is the method used in previously published results. (35) For future clinical applications image cytometry (IC) is an alternative technique applicable to paraffin sections and has been recently shown to be comparable to flow cytometry in BO. (42) Hence in the future, the 3-biomarker panel could be applied from a single diagnostic biopsy stored in formalin.

Since molecular events and mutations occurring in BO are not distributed uniformly within BO, (25, 26) we postulated that use of one or a few random biopsies to assess biomarkers could lead to sampling error. In recent years, a large effort has been invested in novel imaging modalities for the detection of inconspicuous neoplasia. AFI is promising, but its applicability in clinical practice has been limited by a high false positive rate. We hypothesized that AFI positivity might correlate with a field of molecular abnormality surrounding or preceding subtle histological changes. Indeed, we found that aneuploidy and p53 abnormalities significantly correlated with AFI positivity independently of dysplasia. DNA is known to be a weak fluorophore, therefore the loss of autofluorescence may be explained by the increased DNA content observed in aneuploidy. Similarly, p53 is a key gene in the control of DNA amplification and proliferation of aneuploid cells. (43) Even though the other biomarker in the panel (cyclin A) was not associated with AFI positivity in non-dysplastic areas, cyclin A can be overexpressed as result of cell cycle deregulation leading to aneuploidy. (44) Inflammation has previously been shown to associate with AFI false positivity. (15) Since inflammatory pathways can drive genetic and epigenetic changes during carcinogenesis in BO, (45) it is possible that the AFI signal, inflammation and biomarkers are all closely related.
In this study, assessment of dysplasia in the AFI-targeted areas relied only on diagnostic biopsies stored in formalin, therefore there is a possibility of sampling error for very focal dysplasia. To reduce this possibility, large AFI+ areas had two or more diagnostic biopsies taken. Since the molecular changes normally precede development of dysplasia and expand over large areas of mucosa,(25) it is reasonable to consider the field of molecular abnormalities to be larger than the focus of dysplasia, and therefore less affected by sampling error. Notably, the new diagnostic tool had the same sensitivity for dysplasia as the Seattle protocol with significantly fewer biopsies. This could be further reduced using image cytometry to assess aneuploidy on the same diagnostic biopsy used for immunohistochemical markers. Therefore, this novel risk stratification approach, which is based on more objectively measurable outcomes, has the potential to overcome several of the major limitations of BO surveillance endoscopy, including the sampling error and the subjectivity of a dysplasia diagnosis. In our study, four pathologists with special interest in BO from three centres were involved. Yet, the agreement for a diagnosis of any grade of dysplasia was moderate (κ-value 0.56). Hence, a binary outcome of a molecular test can prove advantageous in this regard. In addition, the small number of biopsies may lead to shorter endoscopic procedures, lower risk of complications and improved cost-effectiveness. From an economic perspective, we estimated that the costs required to assess the 3-biomarker panel (aneuploidy by IC + IHC for p53 and cyclin A) on biopsies targeted by AFI were similar to the costs of the Seattle protocol and these costs would come down with high throughput assay techniques (data not shown).

This is a cross-sectional study designed to assess the ability of biomarkers to diagnose prevalent dysplasia and therefore we did not set out to analyze follow up data and look at prediction of future cancer risk by biomarkers. However, it is notable that among the ten patients in the training cohort with a high risk biomarker profile (≥2 abnormal biomarkers) and no evidence of HGD/EC at the time of the endoscopy (Figure 4), six of them (60%) had pathological progression within six months (four from LGD to HGD/EC, one from ID to EC and one from ID to LGD). Assuming this could have been prevalent disease missed by sampling error, this confirms that biomarkers overcome this limitation of the Seattle protocol.

This study has several strengths. It is the first study designed prospectively to assess a pre-defined group of multiple biomarkers in a large cohort of patients with BE. A single laboratory assessed a large panel of biomarkers that had previously been studied by independent groups in different patient cohorts. To our knowledge, this is the largest imaging study in BO and it has a sample size comparable to other biomarker studies. (24, 35) Finally the endoscopic protocol was carefully monitored to guarantee proper training and strict adherence.

However, this study has some limitations. Only approximately 70% of patients could enter the per-patient analysis in the original database (112 out of 157). This is due to the fact that at the start of the study we lacked information about which of the 9 biomarkers would outperform the others in the statistical analysis. Therefore, since not all the AFI+ areas were large enough to allow for three research biopsies, we evenly distributed different biomarker analyses among the available biopsies and then used a combination of MI and bootstrap resampling to deal with missing data. (38) However, all patients included in the validation cohort could be fully assessed.
with the 3 biomarkers, suggesting that a smaller panel is clinically feasible. Furthermore, the patient cohorts were enriched for dysplasia, therefore they do not reflect the general BO population. However, enrichment for high risk patients was necessary to guarantee an adequate number of pathologic outcomes to correlate with biomarker positivity. Moreover, we cannot exclude that the improved diagnostic accuracy of biomarkers on AFI+ areas (Figure 3) is influenced by the higher number of AFI+ areas sampled compared to AFI- regions. In order to maximize the molecular information obtained, without significantly biasing the performance of the Seattle protocol and exceeding the overall number of research biopsies permitted by the ethical committee, we aimed to sample at most 4 AFI+ and one AFI- area per patient and. This notwithstanding, the ratio between AFI+ and AFI- areas was 1.6:1 in the training cohort and 2.1:1 in the validation cohort, hence we believe that this had a small impact on the final results. An additional limitation of this study is that AFI is not compatible with all the endoscopic technologies available across the world. We believe that this study has paved the way for a new diagnostic approach based on the integration of endoscopic and molecular data, and in the future other advanced imaging modalities could be used to target biopsies for biomarker assessment. The advantage of AFI is that, like chromoendoscopy, the assessment of a colour-coded images is relatively easy and our data on the reliability of AFI signal interpretation confirmed a good level of agreement among endoscopists. Finally, although the exclusion of patients with short segments makes this study mostly relevant to patients with long segment of BO, we believe that the latter group of patients is the one that particularly benefits from red-flag endoscopic techniques and biomarkers due to the higher rate of sampling error and number of biopsies compared to short segments of BO.

In conclusion, this study provides evidence that a 3-biomarker panel on AFI-targeted biopsies has equivalent diagnostic accuracy for dysplasia compared to the current gold standard with a significant reduction in the number of biopsies required.

ACKNOWLEDGMENTS

We would like to thank Stephen Meltzer and Zhe Jin (John Hopkins University, Baltimore, MD) for advices on methylation assays; Caryn Ross-Innes for help with flow-cytometry histogram interpretation; Beverly Spencer and Roberto Cayado-Lopez (Addenbrookes Centre for Clinical Investigation, Cambridge) for their help in the endoscopy unit; Irene Debiram and Sarah Hilborne (MRC, Hutchison Research Centre, Cambridge, UK) for their help with patient recruitment; Anna Petrunkina (MRC, Cambridge Institute for Medical Research, Cambridge, UK) for help with flow cytometry; Ian McFarlene and Nicolas Zacchi (Genomics CoreLab, Cambridge Biomedical Research Centre) for help with LOH analysis. Statistical methods

In order to identify a biomarker panel that could predict histological outcome, we used a bootstrap resampling method (1) and took 100 bootstrap samples for each MI dataset and the original database. For each bootstrap sample, we tested individually the 512 different combinations of 9 biomarkers for their association with HGD/EC. Out of the 512 possible models, the best one was selected according to the Akaike information criterion (AIC) of a logistic regression model. In order to correct for potential patient effects when multiple AFI-targeted areas derived from the same patient, they were included as random effects in the model. For each biomarker we calculated the bootstrap inclusion frequency, which was defined as the number of times the biomarker was selected in the 100 best models. The biomarkers with a median inclusion frequency of at least 90 over the imputed datasets and original database were selected for the biomarker panel. (2) The predicted probability of dysplasia for each endoscopic area obtained from a logistic regression with the selected biomarker panel as predictor was used to generate the receiver operating characteristic (ROC) curves to evaluate the diagnostic accuracy of the panel and the area under the ROC curve (AUC) was reported.

For the purpose of the per-patient analysis, in patients with at least one AFI+ area and one AFI- area two datasets, called AFI+ and AFI- dataset, were created. In the AFI+ dataset, each biomarker was assigned a positive outcome, if the biomarker was positive in at least one AFI+ area, and negative if negative in all AFI+ areas. An identical process was followed for the AFI- dataset. The histological diagnosis for a patient was the overall histology (see biopsy and histology section). A logistic regression model, with the selected biomarker panel as predictor, was fitted using patients from a bootstrap sample and was then validated in the patients that were not selected in the bootstrap sample. This process was repeated 2000 times separately for the AFI+ and the AFI- datasets, resulting in 2000 AUC values for each dataset, which were compared in a paired t-test pairing bootstrap samples from the AFI+ and AFI- datasets. This comparison was done in all the 5 imputed databases and the original database.

To validate the biomarker panel selected in the per-biopsy analysis in the per-patient analysis, we applied a simple counting approach to the original database. For each possible panel of two or three biomarkers, a patient was predicted as HGD or EC if the number of positive biomarkers in the panel reached a certain cut-off point. We calculated sensitivity and specificity of each panel for a diagnosis for HGD/EC based on different cut-off points. The best biomarker panel was defined as the one with the highest accuracy (average of sensitivity and specificity). This process was repeated in 2000 bootstrap samples from the original database and the mean and standard deviation of the accuracy was reported for each panel at different cut-off points.

### Supplementary Table 2

Twenty best panels of biomarkers for the diagnosis of HGD/EC from a total pool of 84 different combinations of 3 biomarkers and 36 combinations of 2 biomarkers with different cut-off values. Cut-off refers to the number of abnormal biomarkers required to yield a positive outcome. For each cut-off the means of the diagnostic accuracy form 2000 bootstrap samples and the standard deviation are represented. Highlighted in bold the best cut-off for each panel.
