ABSTRACT

Objectives
Rheumatoid arthritis (RA) is a prototypic chronic inflammatory disease with a debilitating course if untreated. A genetic predisposition for RA is known, and its occurrence is associated with the presence of autoantibodies in the serum as well as environmental factors. It is unknown if smoking and overweight are contributory factors for developing RA in individuals with RA-specific autoantibodies in the serum.

Methods
Fifty-five individuals at risk for developing RA, based on the presence of RA-specific autoantibodies in the serum, who never had any evidence of arthritis upon physical examination, were followed over time. Smoking was assessed as being never or ever smoker, and body mass index (BMI) as <25 (normal) or ≥25kg/m² (overweight). Clinical endpoint was the occurrence of arthritis. Proportional hazard regression analysis was performed to investigate the potential of (combinations of) variables in predicting the onset of arthritis over time.

Results
After a median follow up time of 13 (IQR 6-27) months, 15 individuals (27%) developed arthritis. Smoking was associated with the development of arthritis (hazard ratio (HR) (95%CI): 9.6 (1.3 to 73.0); p=0.029). Overweight was, independently of smoking, associated with arthritis (HR (95%CI): 5.6 (1.3 to 25.0); p=0.023). The overall arthritis risk of 28% after a median of 27 months follow up increased to 60% in individuals with a smoking history combined with overweight.

Conclusions
This is the first prospective study showing that smoking and overweight increase the risk of development of arthritis in a cohort of autoantibody-positive individuals at risk for developing RA. These results show the importance of life style factors in development of RA and should be critically evaluated in future clinical research aimed at disease prevention.
Rheumatoid arthritis (RA) is an immune-mediated inflammatory disease characterized by inflammation of synovial joints, often resulting in degradation of articular cartilage and bone, ultimately leading to joint deformities. If untreated, RA leads to disability, loss of quality of life, and work loss. RA causes premature death due to cardiovascular disease, analogous to diabetes mellitus and the impact of RA on costs for society is huge. The treatment of established RA is promising but expensive; therefore the need for prevention of RA, if possible, is obvious.

The etiology of RA, though largely unknown, is considered multifactorial: a family history of RA and the presence of MHC class II genes and PTPN22 increase the susceptibility of RA; the presence of rheumatoid factor (RF) and anti-citrullinated protein-antibodies (ACPA) point to a contribution of autoimmunity mechanisms, and environmental factors such as smoking and obesity, and their interactions with genetic factors, have been considered important.

Recent research has discovered that circulating autoantibodies and increased acute phase reactants can precede the clinical onset of RA, but only a minority of individuals with RA-specific autoantibodies actually develops clinically manifest RA. The detection of these autoantibodies, however, may define patients with systemic auto-immunity associated with RA without clinical evidence of arthritis, who are at risk of developing RA. In this prospective observational study the contributory role of the modifiable factors smoking and overweight on the development of arthritis in autoantibody-positive individuals at risk for developing RA was investigated.

**METHODS**

**Study subjects**

Individuals with either arthralgia and/or a positive family history for RA, but without any evidence of arthritis upon thorough physical examination, who were positive for IgM-RF and/or ACPA, were included in the study between June 2005 and August 2010. IgM-RF was measured using IgM-RF ELISA (Sanquin, Amsterdam, the Netherlands (upper limit of normal (ULN) 12.5 IU/mL)) until December 2009 and thereafter using IgM-RF ELISA (Hycor Biomedical, Indianapolis, IN (ULN 49 IU/mL)). ACPA was measured using anti-CCP2 ELISA CCPlus (Eurodiagnostica, Nijmegen, the Netherlands (ULN 25 kAU/L)). These individuals were recruited via the outpatient clinic of the department of Clinical Immunology and Rheumatology of the AMC, Amsterdam, via the Rheumatology outpatient clinic of Reade, Amsterdam, or via testing family members of RA patients seen at the outpatient clinic or at public fairs across the Netherlands. The study was performed according to the principles of the Declaration of Helsinki, approved by the institutional review board, and all study subjects gave written informed consent.

**Study design**

At baseline, demographic parameters were obtained as well as environmental and clinical parameters. Overweight was defined as a body mass index (BMI) ≥25kg/m², according to the World Health Association (fact sheet n°311). A detailed smoking history and smoking-status using number of ‘pack years’ was assessed, and smoking status was assigned
as being a never smoker or an ever smoker. One pack year was defined as smoking 20 cigarettes per day for one year.

Study subjects were followed over time until January 2012. Annual study visits were performed. The development of arthritis, defined as a painful and swollen joint, was the endpoint of this study. In individuals with suspected arthritis an extra visit was performed, at which the presence of arthritis was confirmed by two independent investigators (MS and DG or MH and DG).

Statistical analysis
Differences between study groups in continuous parameters were analyzed using t-test or Mann-Whitney U-test if appropriate. Categorical data were analyzed using Chi-square test.

Prediction analysis for arthritis-onset was performed using proportional hazard regression analysis (Cox-regression). Follow-up duration was defined as the time between inclusion in the cohort and the onset of clinically manifest arthritis, or between inclusion and January 2012 (censored). After univariate analysis, variables with p-value <0.2 were selected for a multivariable analysis (forward and backward selection procedures). Meaningful statistical interactions were excluded upfront.

Statistical analysis was performed using PASW Statistics 18 (SPSS Inc, Chicago, Il).

RESULTS
Cohort description
Fifty-five autoantibody-positive individuals were included in the study (51 were referred to rheumatology outpatient clinics because of arthralgia, and 4 subjects without arthralgia were tested because of a positive family history for RA). Nineteen individuals were solely IgM-RF-positive, 22 were solely ACPA-positive and 14 were positive for both autoantibodies. Individuals were followed for a median duration of 27 (IQR: 14-47; range 1-75) months.

Fifteen of the 55 individuals (27%) developed arthritis during follow up after a median duration of 13 (IQR: 6-27, range 0.5-47) months. Of the 15 patients who developed arthritis, 11 fulfilled the 2010 ACR/EULAR criteria for RA\textsuperscript{17, 18} at arthritis onset and 3 were initially diagnosed as having undifferentiated arthritis (UA) but fulfilled the RA classification criteria later on (6 fulfilled the 1987 ACR criteria for RA [20] at arthritis onset and 1 later on). For clinical parameters at arthritis onset as well as baseline see online supplementary Table S1. One patient who developed arthritis fulfilled the ACR classification criteria for osteoarthritis (OA) of the hand\textsuperscript{19}, but not for RA. This patient received non-steroidal anti-inflammatory drugs resulting in a permanent remission of clinical signs and symptoms of arthritis. Of the 14 patients ultimately fulfilling the classification criteria for RA, 2 did not receive disease-modifying antirheumatic drugs (DMARDs). One patient refused conventional treatment and used alternative medicines and the other patient refused treatment because of transient mono-arthritis for which he was closely monitored. Seven RA patients were treated with DMARD monotherapy, 2 with a combination of two DMARDs, 1 with a combination of a DMARD and anti-TNF therapy and 1 was included in a clinical trial evaluating the effects of anti-TNF therapy in early arthritis. After a median follow up of 18 (range 0-60) months
3 RA patients developed RA-erosions on X-ray (the 2 patients who did not receive DMARD therapy and one patient treated with DMARD monotherapy).

**Increased percentage of smoking and overweight in autoantibody-positive individuals who develop arthritis after follow up**

The percentage of ever smokers and individuals with BMI ≥ 25 kg/m² was higher in the group that developed arthritis than in the group that did not (93% vs 53%; p=0.005 for ever vs never smoking and 87% vs 45%; p=0.006 for individuals with a BMI ≥ 25 kg/m² vs those with a BMI < 25 kg/m²). The percentage of individuals who developed arthritis was 38% in past smokers (n=21) versus 43% in current smokers (n=14) (p=0.778 for the comparison between past and current smokers), compared to 5% in the never smokers (n=21) (p=0.019 for the comparison between never smokers and past/current smokers). IgM-RF- and ACPA-status and levels were comparable between individuals who developed arthritis versus those who did not (see Table 1).

**Smoking and overweight are predictors for the development of clinically manifest arthritis**

In the proportional hazard regression analysis, ‘ever smoking’ was associated with the development of clinically manifest arthritis (HR (95%CI): 9.6 (1.3 to 73.0); p=0.029) (Table 2).

* 7 Individuals have been at risk for arthritis development for a shorter period of time: two patients have started with hydroxychloroquine for arthralgias, and two with anti-TNF therapy because of a diagnosis of ankylosing spondylitis (n=1) or Crohn’s disease (n=1). Three individuals were lost to follow up after some time.

* Smoking history: never smoked: 0 pack-years; ever smoked: >0 pack-years

BMI: body mass index; IgM-RF: IgM-rheumatoid factor; ** Only in smokers; *** only in positive individuals: low positive: ≤3 times upper limit of normal (ULN), high positive: >3 times ULN (according to the 2010 ACR/EULAR criteria for RA\(^{17,18}\)); $ Using Chi-square test for frequencies of low and high positivity of IgM-RF in the two outcome groups; ACPA: anti-citrullinated protein antibodies

P-values < 0.05 in bold.
Only one individual who never smoked developed arthritis over time. There was no difference between past and current smokers with regard to the onset of arthritis (p=0.677). The relationship between smoking and the development of arthritis was not confounded by any of the other variables measured (data not shown). Besides smoking, BMI ≥ 25 kg/m² at baseline was associated with the development of arthritis (HR (95%CI): 5.6 (1.3 to 25.0); p=0.023). In the proportional hazard regression analysis smoking and BMI independently conferred an increased risk on clinically manifest arthritis. Of importance, BMI did not significantly correlate with smoking status (p=0.472) and within the group of ever smokers BMI was significantly higher in the subgroup of individuals who developed arthritis compared to the group who did not (28.1 (27.3-34.0) (median (IQR)) vs. 24.6 (21.7-28.7): p=0.010).

In this cohort IgM-RF positivity was not associated with the development of arthritis, and ACPA-positivity showed a trend towards a predictive association (HR (95%CI): 2.7 (0.8 to 9.7); p=0.119), but did not have predictive value over and above smoking and/or BMI. Of note, subjects were selected based on being positive for IgM-RF and/or ACPA, which limits the predictive interpretability of IgM-RF and ACPA in this cohort. Other clinical parameters were not associated with the development of arthritis (data not shown).

When combining smoking and BMI the frequency of arthritis development was significantly higher in ever smokers with BMI ≥ 25 kg/m² compared to the other 3 categories (p=0.001) (see Table 3).

In conclusion, when performing proportional hazard regression analysis the combination of being an ever smoker with BMI ≥ 25 kg/m² resulted in an increase of the

**DISCUSSION**

The results presented here show that modifiable lifestyle factors such as smoking and overweight may importantly contribute to the onset of clinically manifest arthritis in autoantibody-positive individuals at risk of developing RA.

The first important observation in this prospective study is the association between smoking and development of arthritis. Smoking has recently been suggested to be a risk factor for developing RA, but so far only association studies have been performed. Our study is the first analyzing the impact of smoking on the development of arthritis by prospectively following individuals with RA-specific autoantibodies without signs of arthritis who are at risk of developing the disease.

Recent studies have suggested that the lung may be an early site of RA-related auto-immunity, supposedly by the effect of smoking on the citrullination of peptides. Interestingly, in a comparable cohort of individuals at risk for RA with elevated ACPA levels and ≥2 RF isotypes without arthritis airway abnormalities were observed similar to those found in RA patients, and significantly more than in autoantibody-negative controls.

In contrast to what has been suggested previously, the high risk for smoking on arthritis development was not dependent on ACPA-status in our study. In addition, we were unable to define ACPA-status itself as risk factor, in contrast to what was observed in another cohort studying 147 autoantibody-positive individuals without clinically
apparent arthritis. This is likely due to the relatively small number of study participants and differences in inclusion criteria between the current study and the previous. Second, overweight appeared to be a predicting factor for arthritis onset, independently of smoking. Thus far, the results of association studies of overweight/obesity and RA have been variable, with different results for ACPA positive and negative RA and males and females. More in general, an association between obesity and inflammation has been clearly demonstrated. Adiposity is characterized by adipocyte hypertrophy, leading to release of stress signals, such as endoplasmic reticulum stress, and production of reactive oxygen species. As a result, inflammatory pathways are activated and inflammatory cells, such as macrophages and CD8+ T-cells, recruited into the adipose tissue. Adiposity is associated with increased production of pro-inflammatory adipocytokines, including leptin, TNFα, interleukin-1 (IL-1), IL-6 and monocyte chemotactic protein-1 (MCP-1), and decreased production of the anti-inflammatory adiponectin. How this systemic pro-inflammatory state would lead to inflammation in the joint needs to be elucidated. It is also possible that pro-inflammatory activity of adipose tissue in the synovial sublining of the joint might be involved. Previous work has shown that articular adipose tissue obtained from RA patients produced pro- and anti-inflammatory (adipo-) cytokines upon activation, with stimulating effects on fibroblast-like synoviocytes.

In our cohort the overall arthritis risk of 28% after a median of 27 months follow up increased to 60% in individuals with a smoking history combined with overweight. This observation was made in a relatively small cohort, suggesting that the effects of smoking and overweight are strong. In comparison, the risk for developing arthritis in never smokers with normal weight was only 2%, showing that life style modification might have important consequences for arthritis development in RA-prone individuals.

The importance of our findings is emphasized by the increased incidence of RA over the last decades, which cannot be explained by genetic factors, but is most likely influenced by environmental factors. Although this study does not demonstrate that smoking cessation and/or weight reduction are effective in reducing the risk of RA, it is obvious that smoking and increased body weight are inherently modifiable lifestyle factors which are also important in other diseases and that modification leads to decreased health risks in general. An intensive prevention program in Finland aiming at dietary changes and smoking cessation has resulted in long-term prevention of cardiovascular diseases which was accompanied by a similar decline in the incidence of RA. Such programs may contribute to the prevention of RA and related co-morbidities and to a decreased socio-economic burden.

The results of this study, if confirmed in larger, independent cohorts, may also help to better define a population at high risk of developing RA based on the presence of RA-specific autoantibodies, smoking history, and overweight. Improved prediction models may facilitate studies aimed at prevention of RA by targeted intervention during the preclinical phase.

A limitation of this study is the relatively small sample size. The effects observed in our cohort provide the rationale for larger studies in independent cohorts to validate the results presented here. Currently we are unable to determine whether smoking and
obesity are crucial for development of autoantibody positive RA in most patients, or whether these factors merely advance the onset of arthritis. We will continue to follow these individuals to address this issue over time.

It should also be noted that we chose to define the presence of arthritis based on clinical assessment by two experienced investigators rather than by imaging, consistent with clinical practice and evaluation in most clinical trials. Of note, the implications of synovitis shown by ultrasound or MRI in the absence of clinical evidence of arthritis are currently still incompletely understood.

In conclusion, the results presented here suggest that preventable factors, such as smoking and overweight, may increase the risk of developing RA in RF and/or ACPA positive individuals.

ACKNOWLEDGEMENTS
We thank our study subjects for participating in the study. The study was supported by the Dutch Arthritis Foundation (grant 06-1-303 and 11-1-407), the Netherlands Organisation for Health Research and Development (ZonMw) grant 200310003, and the IMI EU funded project BeTheCure n° 115142.
