ABSTRACT

Objective: To investigate the influence of calcium hydroxide (Ca(OH)₂) on susceptibility to disinfection with sodium hypochlorite (NaOCl) of biofilm bacteria.

Methods: Monospecies biofilms of eight Enterococcus faecalis strains were subjected to a 2-h challenge with Ca(OH)₂. After a recovery phase, the biofilms were treated with a concentration of NaOCl that was lower than the minimum inhibitory concentration. In a metabolic assay, the efficacy of NaOCl disinfection in Ca(OH)₂-challenged biofilms and unchallenged biofilms was evaluated. The data were analyzed with Mann-Whitney U and Kruskall-Wallis tests. A P value of less than 0.05 was considered statistically significant.

Results: There were marginal differences in susceptibility to NaOCl among the E. faecalis strains. After the Ca(OH)₂ challenge, seven strains remained equally susceptible to NaOCl disinfection whereas one strain became more resistant to NaOCl (P = 0.03).

Conclusion: After a Ca(OH)₂ challenge, in general E. faecalis remained equally susceptible to disinfection with NaOCl.

Keywords: Biofilm, calcium hydroxide, disinfection, endodontic

INTRODUCTION

Biofilm infection of the root canal system (RCS) accounts for almost all cases of apical periodontitis. Biofilms are complex aggregates of microorganisms attached to a surface and in which the microorganisms are embedded in a matrix of self-produced extracellular polymeric substances. In most biofilms, the matrix consists of over 90% of the dry mass. The matrix protects organisms against desiccation, biocides, some antibiotics, host immune defenses, etc. (1). These biofilms play an essential role in the creation and maintenance of periapical lesions by both the production of products that are responsible for tissue breakdown and the stimulation of the immune system resulting in an inflammation that needs to be treated.

An important aspect of root canal treatment is to disinfect the RCS by removal of infected tissue using rotating instruments followed by irrigation of an disinfecting agent such as sodium hypochlorite (NaOCl). It is well-known, however, that bacteria remain in the canal space after this instrumentation and irrigation. Thus, many clinicians use a calcium hydroxide (Ca(OH)₂) paste as a temporary root canal dressing to gain additional disinfection and to prevent regrowth of remaining bacteria in between two treatment sessions (2, 3).

The use of Ca(OH)₂ is somewhat questionable. Bacteria can still be recovered from root canals after endodontic treatment with Ca(OH)₂ (4). Also, in in-vitro biofilm studies, the disinfecting efficacy
of Ca(OH)$_2$ seems to be limited (5, 6). Moreover, the complex anatomy of the RCS hinders disinfecting agents from penetrating the entire pulp space and in a histological study residual biofilms were found in niches of the RCS after Ca(OH)$_2$ (7). Therefore, it is interesting to study the effect of Ca(OH)$_2$ on residual biofilms.

Previously, it was shown that Ca(OH)$_2$ causes changes in the configuration of the biofilm matrix (6, 8). Enterococcus faecalis has been associated with failed endodontic treatments (9). One study reported that E. faecalis still formed biofilms in the presence of Ca(OH)$_2$ and that the bacteria were encompassed in an even denser matrix. Moreover, approximately 90% of these cells were viable (8). Another study showed that a dense flocculation occurred in dual-species biofilms of E. faecalis and Pseudomonas aeruginosa after a treatment with Ca(OH)$_2$. Also, there was only a factor 100 reduction of viable cells in these biofilms, which contained on average 3×10$^8$ cells (6). It has also been reported that E. faecalis can produce more biofilm mass and protein in response to high pH or sub-inhibitory doses of antimicrobials (10, 11).

From the literature we know that calcium, which is released when Ca(OH)$_2$ is solubilized in water, stimulates the formation of extracellular polysaccharides (EPS) and that it increases the yield strength of biofilms (12, 13). Plus, a high pH favors the uptake of calcium in the EPS (14).

The above-mentioned in-vitro observations combined with the clinical findings support the theory that Ca(OH)$_2$ may stimulate the formation of a more dense biofilm of E. faecalis that may be less sensitive to disinfection in a subsequent treatment session. The formation of a dense matrix or an increase in the coherence of the biofilm matrix can protect the bacteria from disinfecting measures. Also, the genetic makeup of the bacteria may be altered by Ca(OH)$_2$ (15). Until now, no literature is available on inadequate Ca(OH)$_2$ treatments and the possible effects on the susceptibility to disinfection of the remaining biofilm bacteria. Therefore, the aim of this study was to investigate the influence of calcium hydroxide (Ca(OH)$_2$) on the susceptibility of biofilm bacteria to disinfection with sodium hypochlorite. The null-hypothesis of this study was that Ca(OH)$_2$ treatment of E. faecalis strains in an active attachment biofilm model does not induce changes in the sensitivity of these biofilms to NaOCl resulting in a more resistant biofilm.

**METHODS**

**Approval**
The ethical committee of Academic Centre Dentistry Amsterdam, ACTA, confirmed that the Medical Research Involving Human Subjects Act (WMO) did not apply to this study and that this study was performed according to the ethical guidelines at ACTA. The reference number is 2017036Waal.

**Medium**

Biofilms were grown in modified semi-defined broth, pH 7.1, with 0.2% sucrose (BMS) whose composition has been previously published (16).

**Biofilm Growth, Treatment and Resazurin metabolism**
The resazurin metabolism assay and the model have been described previously (17). It consists of a standard 96-well microtiter plate and a lid with 96 polystyrene pegs that fit into the wells (TSP; Nunc, Roskilde, Denmark).

The origins of the E. faecalis strains can be found in Table 1. E. faecalis strains E1, E2, E3, AA-OR34 and OS16 originated from oral rinses and were kindly provided by Christine Sedgley (18). Strains ER3/2s and ER5/1, which have not been published before, also originated from the Sedgley lab and were isolated from orthograde retreatment. Strain V583 (ATCC700802) was used as reference strain. All strains were maintained in stocks at -80°C, and fresh cultures were obtained by the addition of 500 µL of frozen stock culture to 5 mL semi-defined medium supplemented with yeast +0.36% glucose and incubation of 6 h in an anaerobic jar (80% N$_2$, 10% H$_2$, and 10% CO$_2$) at 37°C (16). By initial optical densities at 600 nm (OD$_{600}$) at culture density 0.8 (Spectramax M2, Sunnyvale, CA, USA) the cultures were in a late log phase and contained approximately 5×10$^6$ cells mL$^{-1}$. After 1:100 dilution with BMS, 200 µL of this inoculant was dispersed per well of a 96-well microtiter plate and the plate was covered with the TSP lid. The medium was refreshed after 18 h. After 24 h, the TSP lid with adhered biofilms was transferred to a 96-well plate with 200 µL well$^{-1}$ BMS or 10% Ca(OH)$_2$ (E. Merck, Darmstadt, Germany) (weight/volume, w/v) in BMS (slurry), pH 12.6 for 2 h. Subsequently, the biofilms were washed twice in 200 µL phosphate buffered saline (PBS) and transferred to BMS for an overnight recovery of the biofilms at 37°C anaerobic. Shortly before the final treatments, the free available chlorine concentration of the NaOCl (Orphi Farma, Lage Zwaluwe, The Netherlands) was verified with an iodometric titration procedure and NaOCl was diluted in demineralized water to obtain 1 or 10 ppm solutions of active chlorine (19). 1 ppm NaOCl appeared to be a sub-bactericidal dose for these particular biofilms and therefore suitable for detecting a possible difference between the groups. When the bio-
The individual strains are arranged from least susceptible to NaOCl (left) after Ca(OH)2 treatment. The majority of the tested strains remained equally susceptible to disinfection with NaOCl. The reference strain, V583, was not different from the oral clinical isolates. The null-hypothesis was therefore accepted.

On the whole, E. faecalis biofilms that had been exposed to Ca(OH)2 were equally susceptible to NaOCl disinfection as the control biofilms (P=0.343). However, when evaluating the strains individually, E. faecalis OS16 was less susceptible to NaOCl disinfection (P=0.03) (Figure 2). These differences were independent of the use of Ca(OH)2.

There were significant differences in the susceptibility to NaOCl between the individual strains of E. faecalis: strain ERS/1 was the least susceptible, whereas AA-OR34 was the most susceptible (Figure 2). These differences were dependent from the oral clinical isolates. The null-hypothesis was therefore accepted significant.

The aim of the present study was to investigate whether susceptibility to disinfection by NaOCl of E. faecalis biofilms would change after treatment with Ca(OH)2. The current results show that, after Ca(OH)2 treatment, the majority of the tested strains remained equally susceptible to disinfection with NaOCl. One strain, OS16, became significantly less susceptible and none of the strains became more susceptible to NaOCl disinfection. The reference strain, V583, was not different from the oral clinical isolates. The null-hypothesis was therefore accepted.

Although, the current model does not resemble the clinical situation, it was specifically designed to investigate our fundamental question about the behavior of E. faecalis after Ca(OH)2 treatment. E. faecalis is a bacterial species often encountered as a recalcitrant organism in unsuccessful root canal treatments. It is well-studied in laboratory experiments and, because of its tenacity, is often used as a target organism in disinfection experiments. It is known to survive high pH (6, 8, 10, 20). The presence of calcium stimulates the formation of EPS in E. faecalis biofilms and this may help bacteria within these biofilms to survive certain antimicrobial conditions (12).
The biofilms were grown on an inert substrate (polystyrene pegs) to exclude any possible interference of dentine. Low sub-inhibitory concentrations of NaOCl were used because the susceptibility of *E. faecalis* before and after Ca(OH)₂ application cannot be measured with clinically applicable NaOCl concentrations. Prior to the current study, sub-bactericidal concentrations and incubation-time of Ca(OH)₂ and NaOCl were established for these *E. faecalis* biofilms. In a previous study, a saturated slurry of 10% Ca(OH)₂ at pH 12.5 was shown to be a non-inhibitory concentration in biofilms. Since the solubility constant of Ca(OH)₂ at room temperature is 1.85 g L⁻¹, an active concentration of approx. 0.2% OH⁻ can be obtained. Commercial Ca(OH)₂ pastes/slurries are sold at higher concentrations (30-35%) but will result in a similarly saturated active concentration of 0.2%. The sub-inhibitory treatment of NaOCl was determined at 5 min 1 ppm, which appeared to be a little higher than previously found in similar biofilms (21). If this model is to be employed for investigating the susceptibility of dual- or multi-species biofilms, the concentration of NaOCl will need to be adjusted depending on the type of species and the age of the biofilms (22). It can be argued that these low concentrations of NaOCl are not representative of the clinical situation, but since compounds such as NaOCl strongly react with tissues within the endodontic canals, these low concentrations are likely to be found in the more remote sites of the RCS. This may be one of the reasons that bacteria survive endodontic treatment.

By using a high-throughput system with resazurin, the number of viable cells for the NaOCl sensitivity assay should be roughly similar. This was one of the limitations of the many studies on antimicrobial properties of Ca(OH)₂; variation in inoculum size (23). It was therefore necessary to recover the biofilms for 16 hours after the Ca(OH)₂ treatment so that the bacterial numbers could be restored to the same number of bacteria in the control biofilms (data not published). A previous study demonstrated that, with Ca(OH)₂, the biofilms stayed attached to the surface (6). Therefore, detachment after Ca(OH)₂ application, resulting in a lower resazurin signal, was not observed. Also, there was no difference between the negative controls of the non-Ca(OH)₂ and Ca(OH)₂ groups. Consequently, there were no indications that the results from this study were biased by experimental errors.

Calcium hydroxide is a chemical compound that has one calcium ion and two hydroxide ions (OH⁻). These OH⁻ ions render the environment alkaline in which many bacteria cannot survive. The presence of the free OH⁻ ion as a radical is assumed to have direct effects on the bacterial membrane, protein denaturation and bacterial DNA damage. Certain issues of Ca(OH)₂, however, have been largely overlooked. OH⁻ ions are reducing molecules and are unstable in a solution as they tend to react with CO₂ or other oxides (24). When OH is consumed, Ca(OH)₂ solubilises and, besides OH⁻, Ca²⁺ ions are released. Ca²⁺ ions are divalent cations and as such they bind to the negatively charged surfaces of bacteria, to dentin and to the EPS of the biofilm matrix. This series of events can explain why (traces of) Ca(OH)₂ are difficult to remove from the RCS after use. The solubilisation of the depot of Ca(OH)₂ in the slurry or paste is a continuous process until the depot has been depleted.

This study was designed for *E. faecalis*. Besides being associated with failed endodontic treatment, *E. faecalis* is easy to culture in vitro and therefore is a suitable test microorganism (9). Many properties of *E. faecalis* have already been investigated. For example, a study of the antimicrobial susceptibility of enterococci isolated from root canal showed that *E. faecalis* can be highly resistant to certain antibiotics (25). Our study, however, is the first to show that, despite the changes that occur in the biofilms after the application of Ca(OH)₂, *E. faecalis* in general does not become more resistant to disinfection by NaOCl. We should realise though, that the present study was performed on mono-species biofilms and it may be that multispecies interaction, which occurs in endodontic biofilms, can result in more resistance to either Ca(OH)₂ or NaOCl (26). It would be interesting to see, in future studies, if our theory holds true when endodontic microcosm biofilms are used. Such a study would possibly also give information about the changes in bacterial composition of the biofilms after the application of Ca(OH)₂.

The current findings are clinically relevant because, after the application of Ca(OH)₂, there are often residual bacteria. Also, *E. faecalis* is often found in such secondary infections. This study has, however, demonstrated that the implications of an inefficient treatment with Ca(OH)₂ may be minor.

**CONCLUSION**

The current results indicate that, after a challenge with Ca(OH)₂, one of eight *E. faecalis* strains became less susceptible to disinfection. However, when using a higher dose of 10 ppm NaOCl, this strain was also inactivated. Seven of eight strains of *E. faecalis* remained equally susceptible to disinfection with NaOCl. Therefore, it appears that, in general, Ca(OH)₂ does not affect the susceptibility of *E. faecalis* to NaOCl.
