ABSTRACT

We present early WHT ISIS optical spectroscopy of the afterglow of gamma-ray burst GRB 050730. The spectrum shows a DLA system with the highest measured hydrogen column to date: N(H I) = 22.1 ± 0.1 at the third-highest GRB redshift z = 3.968. Our analysis of the Swift XRT X-ray observations of the early afterglow show X-ray flares accompanied by decreasing X-ray absorption. From both the optical and the X-ray spectra we constrain the dust and gas properties of the host galaxy. We find the host to be a low metallicity galaxy, with low dust content. Much of the X-ray absorbing gas is situated close to the GRB, whilst the H I absorption causing the DLA is most likely located further out.

Key words. gamma rays: bursts – galaxies: distances and redshifts – cosmology: observations

1. Introduction

Gamma-ray bursts (GRBs) have proven to be excellent probes of the distant Universe. High luminosity GRB afterglows allow absorption line studies of the ISM at high redshift to at least z = 4.5 (see Andersen et al. 2000). The launch and successful operation of the Swift satellite means more GRBs are being localised and afterglows studied. Subsequently, the number of high redshift bursts suitable for host galaxy spectral studies has dramatically increased. Deep observations of afterglow positions have detected host galaxies in almost all cases (e.g. Conselice et al. 2005). Most hosts are compact, actively star-forming galaxies and, where the relevant data are available, are found to have low metallicity and low intrinsic extinction (e.g. Berger et al. 2003; Tanvir et al. 2004; Christensen et al. 2004). However, in a few cases, radio/submm observations of hosts give a star-formation rate (SFR) which is of order a few to ~100 times larger than rates derived from optical estimators such as the line luminosities of Hα and [O II] or the 2800 Å restframe UV continuum flux (e.g. Berger et al. 2003). This may be caused by strong dust obscuration, but neither spectra nor colours of hosts show strong internal extinction. Afterglow spectroscopy provides a unique window on the near environment of GRBs (e.g. GRB 021004, Schaefer et al. 2003; Fiore et al. 2005; Starling et al. 2005), allowing us to probe the absorbing dust and gas properties in more detail. In this Letter we present optical and X-ray spectra of GRB 050730, discovered by Swift on July 30th 2005, 19:58:23 UT (Holland et al. 2005) and lying at a redshift of z = 3.97 (Chen et al. 2005a; Rol et al. 2005), in which we study the circumburst gas and dust properties.

2. The optical afterglow spectra

2.1. Observations

During the afterglow phase of GRB 050730, we acquired spectra using the Intermediate-dispersion Spectroscopic and Imaging System (ISIS) on the William Herschel Telescope. The R316R and R300B grisms were used on the red and blue arms respectively. Two observations were done sequentially, at the parallactic angle, with exposure times of 1260 and 1800 s. The first observation started at 22:57 UT at airmass ~2.73 (midpoint 0.132 days after burst), the second at 23:19 UT (midpoint 0.145 d) and airmass ~3.4. The seeing quality at the high airmasses required the slit width to be widened to 2.5 arcsec. Conditions during the observations were not photometric. These factors mean that our absolute flux calibration is not reliable, but the relative calibration should not be affected.
Both spectra have been reduced using the data reduction package IRAF following standard procedures. A Galactic extinction correction of $E(B-V) = 0.049$ (Schlegel et al. 1998) was applied. The wavelength resolutions of blue- and red-arm spectra respectively are 8.7 and 8.1 Å. The signal to noise per pixel, measured at 6800 Å, is 27 in the first and 17 in the second spectrum.

### 2.2. Results

The spectrum, shown in Fig. 1, is rich in line features at $z = 3.97, 3.56$ and 1.77. A strong Damped Lyman-Alpha absorption system (DLA) is present; here we focus on this and a selection of metal lines presumed to originate in the GRB host galaxy. We fitted a power law continuum corrected for Galactic extinction to the $6500-7500$ Å region of each spectrum, excluding the absorption lines, and find an epoch averaged slope of $\beta = -1.34 \pm 0.21$ (2σ formal fit error). We tested for any departure from a pure power law due to host-galaxy extinction: fitting MW, LMC and SMC extinction curves (Pei 1992) all result in epoch averaged $A_V = 0.01$. The optical/IR spectral slope from published BVRIJ photometry extrapolated to a common epoch using a temporal decay slope of 0.89 (Haislip et al. 2005; Holman et al. 2005; Cobb et al. 2005; Blustin et al. 2005) gives $\beta = -1$, consistent with the spectral analysis but not very constraining.

Despite the moderate dispersion of the ISIS 300 grisms, the damping wings of the host galaxy DLA are clearly visible. In fact, the determination of $N$(H I) in DLAs based on long slit spectra is considerably simpler than for echelles. Since the damped profile may extend over many spectral orders in a typical echelle, accurate combination and flux calibration can be troublesome. Using the Starlink software DIPSO, we determine log $N$(H I) = 22.1 ± 0.1 (see Fig. 1). Taking Ly$\beta$ into account did not lead to a more accurate determination of $N$(H I), and the error on our fit is dominated by uncertainties in the determination of the power law continuum. The $N$(H I) value is consistent with, although slightly lower than, that reported by Chen et al. (2005b). This high value (the first DLA to break the $10^{22}$ atoms cm$^{-2}$ barrier) continues the trend amongst GRB DLAs towards very high neutral hydrogen columns (e.g. Jensen et al. 2001; Hjorth et al. 2003; Vreeswijk et al. 2004).

Although our spectra do not enable as detailed a study of the metal lines as is possible via echelle observations (e.g. Chen et al. 2005b), we briefly comment on a selection of these. Detection limits are quoted at the 3σ level. Although we detect both S II $\lambda \lambda 1253, 1259$, both lines are likely to be at least partially saturated. In addition, the weaker S II $\lambda 1253$ line which potentially offers a better limit on $N$(S II) is blended with another (unidentified) feature (Chen 2005, private communication). We determine an upper limit of $[S/\text{H}] < -2.0$ based on the absence of the weaker S II $\lambda 1250$ Å line\(^1\), in good agreement with Chen et al. (2005b). Similarly, from the Fe II $\lambda 1608$ line which is partially saturated and the unidentified Fe II $\lambda 1611$, we determine $-2.9 < [\text{Fe}/\text{H}] < -1.9$.

\(^1\) A search for variability in line features between our two spectra, separated by ~25 min, revealed no significant changes (see on-line table for details), neither did the $N$(H I) column vary.

### 3. The absorbed X-ray afterglow

#### 3.1. Observations

We have analysed the early Swift XRT data, to look for evidence of intrinsic absorption in the X-ray spectrum. The XRT data consist of Windowed Timing (WT) mode data for the first orbit (133 to 793 s after the trigger) and start of the second orbit, and Photon Counting (PC) mode data for later orbits. The data were reduced using the standard pipeline for...

---

\[^1\] S abundance of log (S/H) + 12 = 7.20 (Grevesse & Sauval 1998).
XRT data within the HEADAS 6.0 package (Swift software version 2.0). WT mode data was extracted using a rectangular region centred on the source, and a similar area in a source-free region of the same image to determine the background level. PC mode data was extracted using a circular aperture, except for orbits 2 to 4 which show evidence of pile-up (count rates ≥0.8 counts s⁻¹) and were extracted using an annular region centred on the source and filtered on grade 0 only. The light curve was obtained between channels 30 and 1000 (spanning ~0.3–10 keV). Spectral analysis was done using XSpec 11.3, with the standard Ancillary Response Function (ARF) files, which estimate the effective telescope area, for PC mode data, and with ARFs based on ray-tracing (“physical”) ARFs for WT mode data which should provide a better calibration at low energies.

3.2. Results

The first orbit shows several flares in the light curve, first reported for this afterglow by Grupe et al. (2005). We have performed a detailed analysis of the spectral evolution of the early-time data. The fitted model consists of a power law plus Galactic absorption (fixed at 3.05 × 10²⁰ cm⁻², Dickey & Lockman 1990) and a variable Galactic-like absorption component with Solar metallicity and z = 3.97. Errors are quoted at the 90% confidence level for 1 interesting parameter. We find evidence for a change in power law photon index, from Γ = 1.52 ± 0.04 at the start of the first orbit to 1.79 ± 0.06 at the end of the orbit (note that Γ = 1 − β). We also find evidence for an excess absorption column, which at the redshift of the burst amounts to an intrinsic column of $N_{\text{H,int}} = (1.4 ± 0.3) \times 10^{22}$ cm⁻². However, around 500 s post trigger, the absorption column abruptly changes, becoming lower by about a factor of 4: $N_{\text{H,int}} = (3.4 ± 2.7) \times 10^{21}$ cm⁻². In the late-time PC mode spectrum the intrinsic column cannot be constrained, setting an upper limit of only $N_{\text{H,int}} ≤ 1.0 \times 10^{21}$ cm⁻², and the power law photon index remains stable at $Γ = 1.77$. We have checked for a possible correlation between the intrinsic $N_{\text{H,int}}$ and $Γ$ in the fit. Contour plots for the intervals 133–503 and 503–793 s post trigger show no evidence for any correlation, confirming the reality of both the drop in $N_{\text{H,int}}$ and increase in $Γ$ (Fig. 2). Interestingly, this happens directly after the peak of the second visible flare, where the light curve intensity has increased by a factor of 3. Given the host galaxy metallicity we measure in the optical spectrum, we adjust the X-ray absorption model accordingly. Using $Z = Z_\odot/100$ for all the elements heavier than He included in the xzphabs X-ray absorption model, the required intrinsic equivalent hydrogen column increases by a factor of ~10 in both cases to $N_{\text{H,int}} = 9.5^{+2.3}_{−1.1} \times 10^{22}$ cm⁻² (first 400 s) and $N_{\text{H,int}} = 2.6^{+1.9}_{−1.6} \times 10^{22}$ cm⁻² (≥500 s post trigger) with approximately the same goodness of fit.

A preliminary analysis of published optical photometry together with the PC mode XRT spectrum has shown the X-ray and optical slopes at 0.19 days ($β_\text{X} = −0.7$ to −0.8, $β_\text{opt} = −1.0$ to −1.5) to likely be incompatible with a position of the cooling break between the optical and xrays, and might suggest the presence of an inverse Compton component; we await the availability of further optical/IR photometry for a full analysis.

4. Discussion and conclusions

4.1. Host galaxy properties

There is a well known relationship between galaxy luminosity and metallicity (e.g. Garnett 2002; Lamareille et al. 2004) which spans 6 orders or more of magnitude in $M_\star$. Tremonti et al. (2004) have recently demonstrated that this relation is driven by an underlying relation between mass and metallicity. The cause of the relationship, they argue, is due to the increased gravitational potential of massive galaxies which enhances metal retention. In the absence of a detected host for GRB 050730 at the time of writing, it is in principle possible to use the luminosity-metallicity (LZ) and mass-metallicity (MZ) relations to predict the $M_\star$ and stellar mass of the host. Both of these relations are best determined locally (e.g. Lamareille et al. 2004), although sizeable datasets have now investigated the LZ relation up to $z = 1$ (e.g. Kobulnicky et al. 2003; Klobulnicky & Kewley 2004). There is clear evidence for evolution in the LZ relation, in the sense that galaxies are more metal-poor for their luminosity at higher $z$ (although see caveats in Kewley & Ellison in prep.). This trend appears to continue both for the LZ and MZ relations up to $z = 3$ (e.g. Shapley et al. 2004; Möller et al. 2004; Erb et al. in prep.), although only the highest mass/luminosity galaxies are bright enough to be included in spectroscopic samples. The lowest metallicity bin in the fitted MZ relation of Erb et al. (in prep.) is $Z = Z_\odot/3$ corresponding to a stellar mass log($M_\star/M_\odot$) ~ 9.5. The metallicity measured from absorption lines in the optical afterglow considered here is $Z = Z_\odot/100$, which indicates that the host is not a massive, luminous Lyman break galaxy (LBG), although Jakobsson et al. (2005) argue that GRB hosts follow
the same UV luminosity function as the faint LBGs. We do note that the MZ relation is based on emission lines. However, HST imaging has shown that GRBs occur in regions of strongest star formation (e.g. Fruchter et al. 2005), justifying our assumption that the absorption lines are formed in the same regions as the higher wavelength emission lines. Combining the measured $N(H) \times \langle 24 \rangle \sim L^{24}$ R. L. C. Starling et al.: Gas and dust around GRB 050730
the same UV luminosity function as the faint LBGs. We do note

$$E(B - V) = N_{\text{H}} \times \langle 24 \rangle \sim L^{24}$$

R. L. C. Starling et al.: Gas and dust around GRB 050730

$$E(B - V) = N_{\text{H}} \times \langle 24 \rangle \sim L^{24}$$

R. L. C. Starling et al.: Gas and dust around GRB 050730

$$E(B - V) = N_{\text{H}} \times \langle 24 \rangle \sim L^{24}$$

R. L. C. Starling et al.: Gas and dust around GRB 050730

4.2. The neutral hydrogen column

GRB 050730 has the strongest DLA seen in a GRB afterglow spectrum, with a hydrogen column density of $N(H) = 22.1 \pm 0.1$. The X-ray absorption at late times scaled to $N_{\text{H}} = 100$ yields a comparable log $N(\text{H}) = 22.4_{-0.2}^{+0.2}$ (assuming the $N_{\text{H}}$ measured at $\sim 500$–$800$ s post burst in the WT mode XRT spectrum can be extrapolated to a few hours post burst). The $N_{\text{H},\text{int}}$ we measure in the early-time X-ray spectra covering $\sim 133$–$500$ s post trigger is about ten times higher than that measured at $t > 500$ s. The change in X-ray absorbing column could be caused by ionisation by the gamma-ray jet, or by the X-ray flares which are suggested to be caused by prolonged central engine activity (Burrows et al. 2005; King et al. 2005).

It should be noted that what is measured in the X-ray model is an equivalent hydrogen column, since primarily metal edges contribute to the X-ray absorption at the redshift of GRB 050730, and that this is highly dependent upon the metallicity assumed (see e.g. Wilms et al. 2000). There will be a contribution to the X-ray absorption from intervening systems, which cannot be disentangled from absorption in the host, particularly given that we do not know the metallicity of the closest intervening system observed in this spectrum ($z = 1.77$). In principle, a lower column very close to the observer could have a similar effect on the spectrum as a large column at high redshift.

The observed X-ray column variability does, however, lead us to conclude that most of the X-ray absorbing gas in GRB 050730 is located close to the GRB. The optical H I column remained stable over the $\sim 25$ min between our ISIS spectra, taken at $0.132$ days since burst, well after the observed X-ray flaring (although the occurrence of X-ray flares at later times cannot be ruled out owing to low count rates). The H I creating the DLA is likely to be located much further away from the GRB, unaffected by the GRB radiation. We would expect to observe destruction by the GRB of dust co-located with the X-ray absorbing gas. Our spectra imply a very low extinction in the host at $\sim 3$ h post burst. Future prompt optical spectra, in conjunction with X-ray observations, are required to investigate this further.
