Plasma-Assisted Synthesis of Monodispersed and Robust Ruthenium Ultrafine Nanocatalysts for Organosilane Oxidation and Oxygen Evolution Reactions

We report a facile and general approach for preparing ultrafine ruthenium nanocatalysts by using a plasma-assisted synthesis at < 100 °C. The resulting Ru nanoparticles are monodispersed (typical size 2 nm) and remain that way upon loading onto carbon and TiO₂ supports. This gives robust catalysts with excellent activities in both organosilane oxidation and the oxygen evolution reaction.

Heterogeneous catalysts often consist of small metal particles dispersed on supports.[1–4] Although many methods have been proposed for their synthesis,[5–7] the most common approach involves impregnating the support with a metal precursor solution, followed by thermal decomposition and reduction at a relatively high temperature.[8–10] The problem is that these steps often cause sintering and/or agglomeration.[28–41] Moreover, many “too-small-to-be-stable” nanoparticles form through the Ostwald ripening mechanism.[12] The result is a broad particle-size distribution, which lowers catalyst performance.[10, 13–15] Alternatively, one can use strong reducing agents, such as sodium borohydride and hydrazine, to convert the precursors into the corresponding metals, but many of these reductants are corrosive and/or toxic and can cause further problems downstream.[16, 17] Hence, most of today’s syntheses of monodispersed nanocrystals are based on colloidal chemical synthetic procedures involving the use of capping agents and spacers, which hamper large-scale applications.

One way to avoid these problems is by using plasma-assisted synthesis.[18, 19] This method produces nanoparticles and metal-supported catalysts from metal precursors.[18, 20, 21] Some of the supported catalysts prepared by the plasma-assisted synthesis method are Au/Y-zeolite,[22] Pt/Y-zeolite,[22] Ptγ-Al₂O₃,[23] Coγ-Al₂O₃,[23] Niγ-Al₂O₃,[24] Pt/Al₂O₃−CeO₂,[25] Co/C,[26] and Fe/C.[26] This method is simple, quick, and compatible with impregnation processes.[27] However, these thermal plasma techniques do not always give good control of the particle size.[28] In these processes, the nanoparticles undergo rapid agglomeration because of the high temperatures, which may result in broad particle-size distributions.[28]

Herein, we report a cold plasma-assisted approach for the preparation of supported ruthenium catalysts.[27–30] This method has excellent support compatibility (we used carbon as well as titania supports), which enables the synthesis of monodispersed and ultrafine Ru nanoparticles. Cold plasma synthesis is solvent-free and ligand-free, giving high-purity nanoparticles. We tested these catalysts in two representative yet different reactions: organosilane oxidation and the oxygen evolution reaction (OER). Previous organosilane oxidations were performed mainly by using metals such as gold,[31–34] palladium,[8, 12] platinum,[25] and rhodium.[35] The costs of these metals are 38, 24, 31, and 285 $g⁻¹, respectively (January 2017).[36] Although ruthenium is much cheaper (1.3 $OZT⁻¹), it has rarely been used for silane oxidation. The OER is the rate-determining step in many important energy-related processes such as water splitting, reversible metal–air batteries, and fuel cells.[40, 41] Ruthenium oxide (RuO₂) is one of the best-performing OER catalysts to date,[12–44] Thus, we decided to focus on Ru catalysts, and in both reactions the catalysts showed high activity and stability.

Figure 1 illustrates the facile preparation procedures for the carbon-supported 5 wt% Ru catalyst (denoted hereafter as Ru-Plasma) by a cold plasma synthesis (detailed experimental procedures are included in the Supporting Information). The low-temperature process (< 100 °C) gave ultrfine and monodispersed Ru nanoparticles on the support. Conversely, conventional calcination requires at least 400 °C to decompose the RuCl₃ precursor (see the coupled thermogravimetric and differential scanning calorimetric analyses in Figure S2 in the Sup-
porting Information). Combined with sequential reduction in H₂, it causes the agglomeration of the Ru nanoparticles.

The powder X-ray diffraction (XRD) pattern of Ru-Plasma in Figure 2a confirms the complete decomposition of RuCl₃ and the formation of metallic Ru after plasma treatment. By comparing with the pattern of commercial 5 wt% Ru on carbon (denoted hereafter as Ru-Conv), we attribute the broad peaks at 2θ = 24.0 and 43.5° to carbon (graphite) and the tiny peaks from 2θ = 38.4 to 44° to metallic Ru. X-ray photoelectron spectroscopy (XPS) also reveals the effectiveness of the plasma synthesis. Indeed, overlapping of the C 1s and Ru 3d core levels poses a challenge upon analyzing the spectrum in Figure 2b, particularly at low Ru loadings. Nonetheless, there is a clear binding-energy shift in the Ru 3d₅/₂ peak relative to its position in the sample before plasma treatment, which implies a decrease in the Ru oxidation state (see inset). We also studied the crystal structure of Ru-Plasma through high-resolution transmission electron microscopy (HRTEM). Figure 2c shows the atom-resolved micrographs of two Ru compound particles; the 2.3 Å d spacing indicates the (100) plane of metallic Ru crystal.

Thanks to the plasma treatment, Ru-Plasma has a highly uniform particle-size distribution. Figure 2d,e shows that nearly all of the Ru nanoparticles have dimensions between 1 and 2 nm. In contrast, the Ru particle-size distribution in commercial Ru-Conv is much wider (see Figure 2f,g). There are many too-small (<1 nm, blue arrow) and too-large (>5 nm, yellow arrow) Ru nanoparticles that reduce performance (more TEM results of Ru-Plasma are included in the Supporting Information). This confirms the hypothesis of sintering by Ostwald ripening; the small particles become even smaller as the big ones grow bigger, a “big-fish-eat-small-fish” effect. In addition, Ru-Plasma has a higher specific surface area (1298 m² g⁻¹) than Ru-Conv (713 m² g⁻¹) according to standard N₂ adsorption measurements, due to its finer nanostructure.

Ru-Plasma showed excellent activity and stability in a number of chemical and electrochemical reactions. We initially performed organosilane oxidation to organosilanol by using water as an oxidant under ambient conditions (see Scheme 1 and Table 1). Our catalyst produced organosilanols selectively. H₂ gas was the sole byproduct, and no disiloxanes were observed, unlike conventional approaches. With dimethylphenylsilane as the model substrate, our Ru-Plasma catalyst showed a turnover frequency (TOF) of 29 min⁻¹ at room temperature. Conversely,
Ru-Convs showed a TOF of only 6 min$^{-1}$ (see Table 1, entry 4), which reflects the presence of less-active sites. At 40 $^\circ$C, the TOF increased to 44 min$^{-1}$ with the Ru-Plasma catalyst, even though we doubled the silane/Ru molar ratio to 2637 (Table 1, entry 2). The reaction proceeded to complete conversion even at a higher silane/Ru ratio of 5274 with a TOF of 37.7 min$^{-1}$ (Table 1, entry 3).

Ru-Plasma was also active for the oxidation of other organosilanes (Table 1, entries 5–9). Control experiments confirmed that no reaction took place in the absence of the catalyst or only with the carbon support. The selectivity to silanol was >99%. No disiloxane was detected, ruling out silanol condensation. Interestingly, the spent Ru-Plasma catalyst retained high activity and selectivity after three consecutive runs, indicating its stability (see the TEM image of the spent catalyst in the Supporting Information). We then prepared titania-supported Ru catalysts by the same synthesis route. These also had monodispersed Ru nanoparticles and showed excellent activity in organosilane oxidation reactions (see the Supporting Information for details), which suggests good support compatibility of the new synthesis approach.

A new catalyst synthesis protocol is much more useful if it can be applied to different reaction scenarios. We therefore examined the performance of the Ru-Plasma catalyst in the electrochemical oxygen evolution reaction. However, the "too-small" Ru nanoparticles corroded if the OER potential was applied (RuO$_4^{2-}$ was soluble in the reaction medium).$^{[42,54]}$ Thus, careful control of the nanostructure of the catalyst is important. Figure S6 shows the cyclic voltammetry (CV) curve of Ru-Plasma in 0.05 M deoxygenated H$_2$SO$_4$. The redox peaks were attributed to the hydrolysis of Ru [Eq. (1)],$^{[53]}$ in agreement with the formation of metallic Ru after plasma treatment.
