Abstract: Experiments on the "B state of benzene in the past have established that this state is conformationally unstable due to vibronic coupling with the E state, and that this instability is critically dependent on the influence of a crystal field and substituents. For the "B state of the free molecule, however, the energy differences and sizes of distortion are not known. Since these quantities are of importance for the interpretation of the spectroscopic and photochemical behavior of benzene, the potential energy surface of the "B state along the two-dimensional deformation coordinate S, was calculated with large ab initio MRDCI calculations, including σ and σ correlation. The results show the hexagonal conformation to be unstable and to lie 800 cm⁻¹ above an almost cylindrical trough. Calculation of spectroscopic observables yields good agreement with the experimentally observed vibrational spacing and Franck-Condon factors.

The geometry of benzene in its lowest triplet state ("B) has received considerable attention since Moffit and Liehr pointed out that, in a static picture, the hexagonal conformation might be unstable because of vibronic coupling between the "B and E states through Σ modes. Low-temperature EPR experiments on benzene in a glassy matrix and subsequent EPR and ENDOR experiments on the C₆H₆ in C₆D₆ crystal established that in the solid state the electron spin distribution in the "B state, indeed, is nonhexagonal. Spectroscopic observations supported this result; most remarkable amongst these was the strong doublet of transitions corresponding to the full-CI space within the A₂ symmetry, of which 3000-800000 configurations of B¹ state, symmetry, of which 3000-8000 are selected using a threshold of 15 μH and selection on the two lowest roots. The resulting "B energy surface is depicted in Figure 1 for three values of the parameter ϕ. For comparison, this figure also contains the surface calculated for the E state component to which "B is coupled. It is clear from this figure that the surface for the lowest triplet state is extremely flat and that the hexagonal conformation is unstable, lying 800 cm⁻¹ above the conformations of minimal energy. The dependence on ϕ, if it exists at all, is very small and much smaller than the stabilization energy. With this

Conformational Instability

Figure 1. Potential energy curves for the \( ^3B_{1u} \) state (---) and the component of the \( ^3E_{2u} \) state (---) to which the \( ^3B_{1u} \) state is vibronically coupled as a function of the \( S_\varphi (\rho, \varphi) \) symmetry coordinate. Energy 0.0 corresponds to the energy of the \( ^3B_{1u} \) state in the hexagonal conformation. \( \varphi = 0^\circ \) and \( \varphi = 180^\circ \) correspond respectively to quinoid and antiquinoid conformations.

in mind we can understand the dependence of the distortion on a crystal field and perturbing substituents\(^4,11\) since these will introduce a \( \varphi \) dependence of the energy that could easily be larger than for the free molecule.

In order to calculate spectroscopic observables, we have to solve a two-dimensional nuclear Schrödinger equation. When the \( \varphi \) dependence of the potential is neglected, which seems justified by our results, the problem is reduced to a one-dimensional differential equation. The vibrational eigenfunctions then are

\[
\chi_{\alpha, \beta} = R_{\alpha, \beta}(\rho) \exp(\imath \varphi)
\]

The radial part of this function was solved variationally.

In Figure 2 the first six calculated vibrational levels are depicted. The energy difference between the two lower levels is 220 cm\(^{-1}\), which compares very well with the experimental difference of 245 cm\(^{-1}\). The 245 cm\(^{-1}\) actually was measured in the presence of a crystal field as a doublet,\(^17\) which agrees with the degeneracy of the \( \varphi = 1 \) level.

One of the remarkable features in the phosphorescence is the strong intensity of the 8.0 emission relative to the 8.0 emission. Using Franck–Condon factors, we derive a ratio of 0.25 in accordance with the experimentally found ratio of 0.16.\(^36\)

In summary, we have been able to calculate a potential energy surface for the distortion of the \( ^3B_{1u} \) state of benzene. The accord of calculated spectroscopic observables with measured ones gives us reason to believe that this surface is a good starting point for the interpretation of the spectroscopy and photochemistry of benzene in its lowest triplet state.

After completion of our manuscript, a paper was published by Osamura,\(^12\) who also investigated the deformation of the lowest triplet state of benzene with results somewhat similar to ours. His work, however, differs from ours in two respects: the correlation was restricted to the \( \pi \) electrons, and only the three energy extrema of the potential surface were considered which occur for the hexagonal, quinoid, and antiquinoid conformations. When the results of ref 12 (which agree with similar, unpublished, calculations made by us) are compared with the results presented here, it appears that the inclusion of \( \sigma - \pi \) and \( \sigma - \sigma \) correlation not only leads to a lowering of the relative energy minima by some 300 cm\(^{-1}\) but, more importantly, also causes the energy difference between the quinoidal and antiquinoidal forms to vanish, in agreement with the evidence provided by EPR experiments.\(^4\)

Because of the anharmonicity of the potential surface and its two-dimensional nature, the frequencies inferred from the second derivatives at the extrema determined in ref 12 express certain trends but cannot be compared with spectroscopic observables.
