Chapter 5

Why seek treatment for TMD-pain complaints? A study based on semi-structured interviews

A. Rollman, R.C. Gorter, C.M. Visscher, M. Naeije
Abstract

About half of the people with TMD-pain complaints seek treatment for their complaints. Comparing experiences and perceptions of people who seek care for TMD-pain complaints (care seekers) with people who do not (non-care seekers) can be an important source of information to improve insight in care seeking. Although questionnaire studies have highlighted some aspects that play a role in the decision to seek care (like pain intensity), much information remains unknown. Semi-structured interviews, on the other hand, allow for an open view and may reveal yet unknown aspects in care seeking. The aim of this study was to assess possible differences between care seekers and non-care seekers with TMD-pain complaints, by using semi-structured interviews. Methods: semi-structured interviews were held with 16 subjects with TMD-pain complaints: 8 care seekers and 8 non-care seekers, matched for age, sex, pain intensity and fear of movement. Subjects were selected from a previously held survey study, with their consent. The interviews were audio-taped, transcribed verbatim and analyzed according to qualitative content analysis. Results: From the analysis, seven themes differentiating care seekers from non-care seekers were identified: catastrophizing, pain management, assertiveness, critical attitude towards healthcare, confidence in medical care, recognition, and adequate referral. Conclusion: Aspects upon which care seekers differed from non-care seekers were mainly person-related characteristics. Next to these characteristics, it appeared that inadequate referrals may play a role in care seeking. Using semi-structured interviews may further improve insight in processes that determine care seeking among people with TMD pain complaints.

Key words: care seeking, health care practitioners, qualitative research, semi-structured interviews, temporomandibular disorder pain
Introduction

Pain in the face or mouth (orofacial pain) is a common pain syndrome, with a prevalence of approximately 13% (range 1-48%) (1). In the acute form, it most commonly arises from a dental origin. Chronic orofacial pain is most commonly associated with a temporomandibular disorder (TMD), but may also arise from other disorders such as a trigeminal neuralgia (2, 3). Even though pain is considered the major motivational factor for individuals to seek healthcare, not all individuals experiencing pain attend a healthcare practitioner. For TMD pain, it is estimated that only about half of the people seek treatment (4, 5). Better insight in people's care seeking behavior for pain can provide essential information to further improve current treatment strategies, which is important especially for those patients who are at risk to develop chronic pain complaints (4).

In two recent studies on subjects with TMD-pain complaints, a wide range of physical, psychological, and social dimensions were measured in both non-care seekers and care seekers, explaining a variety of reasons for care seeking (6, 7). It was shown that higher levels of pain intensity increased the probability of seeking care (6, 7). Besides pain intensity, also higher levels of fear of jaw movement were positively related to care seeking (7). However, these items could only partly explain why some subjects seek care while others do not, implicating that other, still unknown aspects play an important role as well.

Since chronic TMD pain shares features with other chronic musculoskeletal pain syndromes (such as low back pain and neck pain) - including modest associations between symptom severity and physical findings, greater prevalence among women, and significant psychological distress (1, 3, 8-10), it is likely, that reasons for care seeking in subjects with TMD pain shares similarities with reasons for care seeking in subjects with other musculoskeletal pain conditions. In literature to care seeking for low back pain (LBP), it has been shown that especially physical symptoms (such as higher pain intensity and physical disability) play a role in the decision to seek care (11, 12). However, also individuals with low physical disability or only mild pain were found to have visited a healthcare practitioner, indicating that indeed other factors are involved in the decision to seek care as well (13).

Both in low-back pain and in TMD-pain studies, the common approach to study care seeking behavior is to use surveys with closed-answer questionnaires. Using semi-structured interviews invites people to speak freely about their personal pain history and may reveal yet unknown aspects that explain why some people seek care while others do not. Qualitative research designs like semi-structured interviews are powerful in discovering perceptions of people that may remain unnoticed in closed-answer questionnaire studies (14, 15). Therefore, the aim of the present study was to assess possible differences between care seekers and non-care seekers with TMD-pain complaints, by using semi-structured interviews among a selection of subjects from a previously held survey study (7).
Material and Methods

Subjects

The subjects in the present study were selected from a larger survey study in which 203 participants with a report of TMD pain participated, among whom were both non-care seekers and care seekers (7). Participants were considered to be “non-care seekers” when they had never sought care for their pain complaint, and “care seekers” when they had visited at least one health care practitioner for TMD-pain complaints in the past. From that study, a sample (N=16) of “non-care seekers” (N=8) and “care seekers” (N=8) was contacted by telephone by the principal investigator (AR) to invite them for a semi-structured interview, and to give informed consent (subjects had given permission to be contacted for future research in the initial survey questionnaire). Because results from the previous survey study (7) had shown that pain intensity (as measured on a characteristic pain intensity scale) (16) and fear of jaw movements (as measured with a fear-of-jaw movement scale) (7) are associated with care seeking, the non-care seekers and care seekers were matched for pain intensity and fear-of-jaw movement. Additionally, the groups were also matched for age and sex comparable to the distribution in the previous survey study (7).

Semi-structured interviews

In alternating rounds, care seekers and non-care seekers were interviewed in a non-clinical environment: either at the participant’s home, at the Oral Kinesiology department’s office, or in a quiet public location, depending on the participant’s preference. Each participant was interviewed for about 30–60 minutes and the interview was digitally audio taped (permission to record was given by the participant in advance). The interviews were held by the principal investigator (AR), who was trained to perform semi-structured interview techniques as described by Kvale (17).

The interviews were designed to enable people to respond in an unrestricted way, allowing aspects to be introduced by respondents and by the interviewer (18). The interviews had the following structure: an introduction in which the principle investigator gave an explanation about the goal of the interview and in which she asked the subject about his or her TMD-pain complaints (like: “How is the pain at this moment?”). After the participant was set at ease and the goal of the interview was made clear, the principle investigator asked a transition question (like: “So, could you tell about what kind of care you sought for this pain”) to bring the conversation to healthcare usage for TMD-pain complaints. Subsequently, when the participant talked about his/her care-seeking behavior, the key-question was asked: “Why did you (not) see a health care provider?”. Subjects were encouraged to describe their motivations to (not) seek treatment in their own words, by the use of open-ended questions by the
interviewer. Furthermore, in each interview, the interviewer asked the participants how each of the following topics was of influence in their care seeking:

- Pain, function limitation, limitations in daily life;
- Healthcare usage for other (pain) complaints;
- Experiences in healthcare usage (eg impression of the expertise of the health care provider);
- Practical matters (taking time off, distance to health care provider, finances);
- Knowledge of possibilities for treatment;
- Social support.

The authors chose these topics because, based on literature (6, 11, 12), it could be expected that they play a role in care seeking. To be sure that the information that was given by the participant was correctly and completely understood, the principle investigator ended the interview with a summary meanwhile inviting the participant to correct or add information if necessary.

Saturation

The interviews of each round of matched care seekers and non-care seekers were analyzed applying the principles of the so-called constant comparative method (19), whereby data collection and analysis occur concurrently, allowing previous propositions to be explored in subsequent interviews. Using this method, data collection continued until no new issues emerged from the interviews (and saturation was achieved) (19). After interviewing 7 non-care seekers and 7 care seekers, no new information emerged. To be certain that saturation was achieved, another non-care seeker and care seeker were interviewed (Total N=16). Again, no new information emerged. Two researchers (AR and RG) were involved in this part of the analysis. AR explored the issues, which were discussed and refined with RG.

Consensus

The audio recordings of each interview were transcribed verbatim. Then, five selected experts (a MSc in Oral Public Health and with dental education background; a psychologist specialized in social dentistry; two psychologists specialized in dentist-patient communication; and a clinical psychologist/ psychotherapist), formed a panel, and completed a consensus procedure, derived from a delphi-consensus method (20, 21). In this procedure, following a series of rounds, agreement in interpretation is achieved. In the first round, the experts were asked to individually read the interviews, without insight in the opinion of the other experts, and to denote differences between care seekers and non-care seekers. Subsequently, the principal investigator made an overview of these differences. In this overview, shared and unique observations of the
experts were categorized in a set of tentative themes. In round two, this overview was provided to each expert individually. The experts were invited to comment on the themes in two ways: First, to indicate whether the descriptions of the themes were adequate reflections of their own observations. If not, they were asked to adapt the formulation in a way that would reflect their observations better. Second, they were asked to indicate whether or not they agreed with the themes that were found by other experts. After the second round, all experts agreed to the themes, and consensus was achieved. The medical ethical committee of the VU University of Amsterdam approved the study (file number 2004/166).

Results

As a result of the matching procedure, the 8 non-care seekers did not differ from the 8 care seekers with respect to age, gender, pain intensity and fear of jaw movements. Both in the non-care seeker group and in the care seeker group, 6 women and 2 men participated (Table 1). All participants that were invited for semi-structured interviews agreed to participate and gave informed consent.

Seven themes emerged that were considered to be different between care seekers and non-care seekers (Table 2). Six themes concerned person-related characteristics; one theme was related to external circumstances. In the following section, these themes are more fully described. Citations, illustrating the description, are written in italic.

Person related characteristics

Catastrophizing: Care seekers interpreted their pain as alarming and too long-lasting. Care seekers appeared to be really concerned about their complaints. They considered the pain as a priority, and an argument to take time off from work: “I went to see my general practitioner. I thought, maybe I have a brain tumor, maybe something is wrong.” [Interview 2]. Non-care seekers, on the other hand, did not consider their pain complaints as alarming and did not consider it a priority: “Taking time off is too much hassle.” [Interview 7]. Even if pain complaints were severe, they tended to accept the situation as it is, as illustrated by the following citation: “The pain is part of me. I read a few things about it and the pain is just part of it, and clicking will not go away. Therefore, I never considered to seek care.” [Interview 6].

Pain Management: Care seekers strongly believed that someone else has the solution for their pain, and, therefore, they aimed at a referral to a health care provider. “I hoped that at an Academic TMD-centre, they would have something special which would make my pain complaints go away. A device…., or whatever…., a new joint…., something to make it normal.” [Interview 13]. Non-care seekers, on the other hand, not only had the tendency to manage their pain themselves; they were convinced that they were capable of doing
so. Some typical formulations were: “I believe that it is something I do when I am stressed, so then I address the tension, what caused it, and I do something about it. It manifests itself here (while pointing at jaw). For someone else this may be the neck. I would first try to figure it out for myself.” [Interview 13]. Or: “I listen to my body so I asked myself, where does the pain come from. I also chewed more chewing gum, felt I wanted that, so then I knew: hey, that is causing the pain. It increased my complaints.” [Interview 9]. Moreover, as opposed to care seekers, non-care seekers made a connection between their facial pain and personal circumstances, such as stress, or other psychological and/or physiological disturbances. Subsequently, they often came up with their own treatment strategies to relief their pain: “Sometimes I give my jaw a massage and I do some exercises, I know that I can help myself.” [Interview 3].

Assertiveness: Care seekers believed it is self-evident to seek care, and they insisted on doctors’ help: “If I have a physical complaint, most of the time I will go directly to the general practitioner.” [Interview 16]. Or: “Although I came for a check-up at the dentist, I was the one who took the initiative to discuss my complaints.” [Interview 12]. On the other hand, non-care seekers do not want to bother someone else with their complaints. They felt uncomfortable when consulting a healthcare practitioner. Non-care seekers tended to keep the pain to themselves and did not want to complain. To them it feels like they were exaggerating when consulting a healthcare professional for their complaints: “That’s me, I don’t like to whine. I know they have many patients that come for every little thing.” [Interview 15].

Critical attitude: Care seekers expressed criticism and were not easily satisfied with accessible care: “Alignment between the departments is missing.” [Interview 2]. Or, “An adequate interview was missing, no good questions.” [Interview 11]. Moreover, as a result of being critical, they were persistent in searching for adequate care. In contrast, non-care seekers did not mention this topic.

Confidence in medical care: Non-care seekers reported little confidence in proper treatment, and rather discussed complaints with friends in a more empathic environment. “To check if my complaint is something serious, I use the Internet, talk to friends, but I do not go to my general practitioner. I wish I could, but there is a lack of empathy.” [Interview 2]. In contrast, care seekers did not mention this topic.

Recognition: Care seekers were glad to get recognition from others for their suffering, and were relieved when they had found fellow-sufferers. “I had such vague complaints; I did not have the idea that this could have to do with my jaws. But when I came into the waiting room, I saw another guy rubbing his temples. Then I thought: I am not the only one, I’m not some kind of nutcase. I am at the right place.” [Interview 15].

External circumstances:

Adequate referral: Care seekers reported to be adequately referred to a health care provider, although often it took a long pathway to get this referral: “After mentioning my
complaints to my dentist, it still took at least half a year before she pointed out this clinic to me […] Before that, I never heard of this kind of care!” [Interview 12]. Non-care seekers, on the other hand, reported that, although the dentist was sometimes aware of their complaints, they were not referred to a health care provider: “My dentist knows that it hurts when I open my mouth, and that I cannot open my mouth widely. He never said anything about it. Probably, I also never discussed it explicitly with him. He never suggested any treatment.” [Interview 5].

Although it was the task of the panel of experts to reveal differences between care seekers and non-care seekers, while reading the interviews, the panel also stressed some similarities between the two groups. These similarities were: all participants used the Internet for information; most participants expressed dissatisfaction with the lack of time the general practitioner showed; and all wished that the general practitioner would have been more directive (or more quickly directive) in referring to a health care provider.

Discussion

The aim of the present study was to assess possible differences between care seekers and non-care seekers for TMD-pain complaints, by using semi-structured interviews. In a previous study, it was shown that pain intensity and fear of movement are related to care seeking (7). This study indicates that care seeking may also be associated with differences in person related characteristics: catastrophizing, pain management, assertiveness, critical attitude towards healthcare, confidence in medical care, and recognition. Moreover, it was found that non-care seekers are not always adequately referred to a health care provider. These results indicate that semi-structured interviews may provide further insight in processes that determine care seeking among persons with TMD-pain complaints.

In this interview study, two methodological aspects may have influenced the results. First, due to the small sample size, one runs the risk that themes that differentiate care seekers from non-care seekers were overlooked. To reduce this risk as much as possible, the constant comparative method was used (19). In this method, the data collection and data analysis occur concurrently, enabling the exploration of previous propositions in subsequent interviews. After seven pairs of non-care seekers and care seekers, no new information came up. Subsequently, an additional couple was interviewed, which did not provide new information either, suggesting that indeed saturation was achieved. A second risk is that personal notions and expectations of the experts analyzing the interviews may have influenced the results (bias). Whereas in most qualitative research studies, one or two experts analyzed the data, (18, 22, 23), in this study the risk of bias was minimized by using a Delphi-consensus method with a panel of five experts (20, 21). Four of them were psychologist, and three of these also professionally active in dentistry, thus providing for an expertise in trained listening skills to an individual’s story, and familiarity with the impact of orofacial problems.

In the few qualitative research design studies to care seeking in subjects with TMD-pain complaints performed so far (18, 22, 23), the motivations and experiences of care seekers only were investigated. A unique aspect of the present study is that not only a group of care seekers, but also a group of non-care seekers was interviewed. Since non-care seekers did not report their complaints at a health care office, and therefore not registered, the recruitment of this control group is difficult. The care seekers and non-care seekers in the present study were selected from a larger survey study (7), in which about 100 people had to be approached face-to-face at public places in order to find one non-care seeker with TMD-pain complaints. Interestingly, the topics that were expected to play a role in care seeking, based upon literature, and discussed in each interview, did not fully differentiate care seekers from non-care seekers in the present study. By including a control group of non-care seekers, a better, more diverse, insight into factors influencing care seeking was obtained than when merely looking at care seekers. The fact that non-care seekers sometimes did not receive treatment for their complaints because of an inadequate referral, could only be found by interviewing non-care seekers (Table 2).
To the best of our knowledge, studies to care-seeking in subjects with TMD-pain (4, 6, 7) or low-back pain (11), including non-care seekers as a control group, always use the technique of closed-answer questionnaires. It is striking to see, that although several biopsychosocial factors were investigated, only the severity of the complaints (pain intensity, pain duration, and disability) was consistently found to be associated with the decision to seek care (4, 6, 7, 11). As the present study is most likely the first to use the technique of semi-structured interviews, participants were invited to talk freely about their personal pain history, resulting in them describing yet unknown aspects of care-seeking. Other than in questionnaire studies, the present interview study revealed that also person-related characteristics play a role in care-seeking. For example, the finding that care seekers seem critical and not easily satisfied about accessible care and persistent in searching for adequate care, was not found earlier in literature. This underlines the strong asset of in-depth interviews: it offers new information on top of what is already known from surveys. It is interesting to speculate on what exactly accounts for the differences between the standardized answering formats and a semi-structured interview format. It is possible subjects have occasionally experienced difficulties identifying themselves with the predefined phrasings, where the semi-structured interviews offered room for a personal choice of words. In this way, semi-structured interviews may have revealed characteristics that were difficult to catch in fixed formats, such as closed-answer questionnaires (24). It is encouraged that in the future, studies with a similar study-design are performed in new samples, both with regard to orofacial and other pain aspects (such as low-back pain), in order to see whether the same themes emerge.

In general, the interviews give the impression that care seekers are more focused on pain than non-care seekers. Care seekers appear more worried, and more often look for solutions externally. Possibly, as a result from expecting solutions from others, they appear assertive, critical and look for recognition. In this study we choose to separate the characteristics as different, rather broad, concepts (pain management, assertiveness, critical attitude and recognition). Future studies could give insight whether these characteristics are a consequence of the subjects' locus of control (internally or externally).

Interestingly, non-care seekers, in contrast to care seekers, appeared not so concerned about their pain (see Table 2), but nevertheless, most of them had chronic pain complaints (see Table 1). This seems to be in disagreement with the fear avoidance model by Vlaeyen et al, which suggests that catastrophizing is an important precursor of chronic pain (25). As a reaction to a painful injury, a vicious circle of pain, catastrophizing, fear of movement, and disability, are thought to lead to the development of a chronic pain condition (25). In favour of this theory is a recent clinical trial showed the therapeutic efficacy of an early biopsychosocial intervention for patients with acute TMD who are at risk of developing chronic TMD demonstrated that pain levels dropped significantly after the biopsychosocial intervention, as assessed at the one-year follow-up (26). Our findings in the non-care seeking group could just be an illustration that the fear-avoidance model is only applicable for patients, and not for
non-care seekers. Nevertheless, health-care practitioners should be aware that the care seekers who visit them for TMD-pain complaints are usually worried about the cause of their pain complaints. Therefore, reassurance should be a standard procedure in counseling patients who suffer from a TMD-pain.

Even though non-care seekers are not so worried about their pain complaints, they might suffer unnecessarily long from these complaints. They keep trying to find a solution on their own (Table 2), while treatment options may be available. Since all participants in this study reported that they searched the Internet for information, proper information on the Internet may help people to find their way to a health care provider. This suggestion is supported by an earlier report on health care seeking behavior on the Web (27), which pointed out that the information found on the Web has a direct influence on the decisions people make about their health care and also on their interactions with the health care practitioners (27). This indicates that TMD-clinics should provide the Internet with high quality, evidence-based information regarding TMD. Moreover, since this study confirmed earlier findings (22), that care seekers experience relief in finding fellow-sufferers (Table 2), patients should be facilitated to come across fellow sufferers. Possibly, and as an addition to a treatment program, group sessions of pain sufferers or Internet communities could offer a platform where patients can meet fellow sufferers. Another finding of this study is that not only person-related characteristics are of influence on the care seeking of subjects with TMD-pain complaints, also external circumstances play a role. Adequate reactions or referrals of healthcare-practitioners, when they encounter patients with TMD-pain complaints, are important. The interviews showed that a non-care seeker may be a non-care seeker because he was not adequately referred (Table 2). Moreover, and in line with a previous study (22), care seekers often expressed to have travelled a long way through the health care system before actually finding their way to a TMD health care provider. This confirms that not every healthcare provider is aware of the treatment possibilities for TMD-problems (28). As suggested by others, clear guidelines and education programs for dentists and other healthcare practitioners should be promoted, in order to increase knowledge on TMD care and TMD-treatment possibilities (29, 30).
Conclusion

From this study several new themes appeared to differentiate care seekers from non-care seekers with TMD-pain complaints. Most of these themes were person related characteristics: catastrophizing, pain management, assertiveness, critical attitude towards healthcare, confidence in medical care, and recognition. Next to these characteristics, it appeared that inadequate referrals may play a role in care seeking. Using semi-structured interviews offers the possibility to increase insight in internal processes that determine care seeking among people with TMD-pain complaints.

Acknowledgements

We would like to thank the collaborating TMD clinics for their help in the recruitment and follow-up of care seekers: Amphia Ziekenhuis Breda, Haga Ziekenhuis Den Haag, Isala Klinieken Zwolle, Medisch Centrum Alkmaar, Stichting Bijzondere Tandheelkunde Amsterdam, and Ziekenhuis Rijnstate Arnhem. We would like to thank all colleagues at the Department of Oral Kinesiology who facilitated this study, with special appreciation to Carlijn van der Lugt and Stanimira Kalaykova for their help with the recruitment of non-care seekers. Especially, we like to thank all participants for their participation in the research. This study was supported by the Institute for Dental Sciences in the Netherlands (IOT).
