ABSTRACT

At least 5 per cent of the massive stars are moving supersonically through the interstellar medium (ISM) and are expected to produce a stellar wind bow shock. We explore how the mass-loss and space velocity of massive runaway stars affect the morphology of their bow shocks. We run two-dimensional axisymmetric hydrodynamical simulations following the evolution of the circumstellar medium of these stars in the Galactic plane from the main sequence to the red supergiant phase. We find that thermal conduction is an important process governing the shape, size and structure of the bow shocks around hot stars, and that they have an optical luminosity mainly produced by forbidden lines, e.g. [O III]. The Hα emission of the bow shocks around hot stars originates from near their contact discontinuity. The Hα emission of bow shocks around cool stars originates from their forward shock, and is too faint to be observed for the bow shocks that we simulate. The emission of optically thin radiation mainly comes from the shocked ISM material. All bow shock models are brighter in the infrared, i.e. the infrared is the most appropriate waveband to search for bow shocks. Our study suggests that the infrared emission comes from near the contact discontinuity for bow shocks of hot stars and from the inner region of shocked wind for bow shocks around cool stars. We predict that, in the Galactic plane, the brightest, i.e. the most easily detectable bow shocks are produced by high-mass stars moving with small space velocities.

Key words: shock waves – methods: numerical – circumstellar matter – stars: massive.

1 INTRODUCTION

Massive stars have strong winds and evolve through distinct stellar evolutionary phases which shape their surroundings. Releasing material and radiation, they give rise to interstellar medium (ISM) structures whose geometries strongly depend on the properties of their driving star, e.g. rotation (Langer, García-Segura & Mac Low 1999; Chita et al. 2008; van Marle et al. 2008), motion (Brighenti & D’Ercole 1995a,b), internal pulsation (see chapter 5 in van Velzen 2010), duplicity (Stevens, Blondin & Pollock 1992) or stellar evolution (e.g. Napoleon’s hat generated by the progenitor of the supernova SN1987A and overhanging its remnant, see Wang, Dyson & Kahn 1993). At the end of their lives, most massive stars explode as a supernova or generate a gamma-ray burst event (Woosley, Heger & Weaver 2002) and their ejecta interact with their circumstellar medium (Borkowski, Blondin & Sarazin 1992; van Veelen et al. 2009; Chiotellis, Schure & Vink 2012). Additionally, massive stars are important engines for chemically enriching the ISM of galaxies, e.g. via their metal-rich winds and supernova ejecta, and returning kinetic energy and momentum to the ISM (Vink 2006).

Between 10 and 25 per cent of the O stars are runaway stars (Gies 1987; Blaauw 1993) and about 40 per cent of these, i.e. about between 4 and 10 per cent of all O stars (see Huthoff & Kaper 2002), have identified bow shocks. The bow shocks can be detected at X-ray (López-Santiago et al. 2012), ultraviolet (Le Bertre et al. 2012), optical (Gull & Sofia 1979), infrared (van Buren & McCray 1988) and radio (Benaglia et al. 2010) wavelengths. The bow-shock-producing stars are mainly on the main sequence (MS) or blue supergiants (van Buren, Noriega-Crespo & Dgani 1995; Perti et al. 2012). There are also known bow shocks around red
supergiants (RSG), Betelgeuse (Noriega-Crespo et al. 1997; Decin et al. 2012), μ Cep (Cox et al. 2012) and IRC−10414 (Gvaramadze et al. 2014) or asymptotic giant branch (AGB) stars (Jorissen et al. 2011; Cox et al. 2012). Bow shocks are used to find new runaway stars (Gvaramadze, Kroupa & Pflamm-Altenburg 2008) and to constrain the properties of their central stars, e.g. mass-loss rate (Gull & Sofia 1979; Gvaramadze, Langer & Mackey 2012), or the density of the local ISM (Kaper et al. 1997; Gvaramadze et al. 2014).

The structure of such bow shocks is sketched in Fig. 1. However, the layers of shocked ISM develop differently as a function of the wind power and ISM properties. The wind and ISM pressure balance at the contact discontinuity. It separates the regions of shocked material bordered by the forward and reverse shocks. The distance from the star to the contact discontinuity in the direction of the relative motion between wind and ISM defines the stand-off distance of the bow shock (Baranov, Krasnobaev & Kulikovskii 1971). The shape of isothermal bow shocks, in which the shocked regions are thin, is analytically approximated in Wilkin (1996).

A numerical study by Comerón & Kaper (1998) compares wind–ISM interactions with (semi-) analytical models and concludes that the thin-shell approximation has partial validity. This work describes the variety of shapes which could be produced in bow shocks of OB stars. It details how the action of the wind on the ISM, together with the cooling in the shocked gas, shapes the circumstellar medium, determines the relative thickness of the layers composing a bow shock, and determines its (in)stability. It shows the importance of heat conduction (Spitzer 1962; Cowie & McKee 1977) to the size of these bow shocks, and that rapid cooling distorts them. The shocked regions are thick if the shock is weak, but they cool rapidly and become denser and thinner for the regime involving either high space velocities or strong winds and/or high ambient medium densities. This leads to distorting instabilities such as the transverse acceleration instability (Blondin & Koerwer 1998) or the non-linear thin-shell instability (Dgani, van Buren & Noriega-Crespo 1996a,b). Mac Low et al. (1991) model bow shocks around MS stars in dense molecular clouds. The bow shock models in Comerón & Kaper (1998) are set in low-density ambient medium.

Models for bow shocks around evolved, cool runaway stars exist for several stellar evolutionary phases, such as RSG (Brighenti & D’Ercole 1995b; Decin et al. 2012; Mohamed, Mackey & Langer 2012) or AGB phases (Waring, Zijlstra & O’Brien 2007b; Mohamed et al. 2012); however, this study considers a single mass-loss rate and does not allow us to appreciate how the wind modifies the bow shock’s shape or luminosity. In addition, van Marle, Decin & Meliani (2014) show the stabilizing effect of a weak ISM magnetic field on the bow shock of Betelgeuse.

In this study, we explore in a grid of 2D models, the combined role of the star’s mass-loss and its space velocity on the dynamics and morphology of bow shocks of various massive stars moving within the Galactic plane. We use representative initial masses and space velocities of massive stars (Eldridge, Langer & Tout 2011). Stellar evolution is followed from the MS to the RSG phase. The effect of the dissipative processes and the discrimination between wind and ISM material allows us to calculate the bow shock luminosities and to discuss the origin of their emission. We also estimate the luminosity of the bow shocks to predict the best way to observe them. The project differs from previous studies (e.g. Comerón & Kaper 1998; Mohamed et al. 2012) in that we use more realistic cooling curves, we include stellar evolution in the models and because we focus on the emitting properties and observability of our bow shocks. We do not take into account the inhomogeneity and the magnetic field of the ISM.

This paper is organized as follows. We first begin our Section 2 by presenting our method, stellar evolution models, including physics and the numerical code. Models for the MS, the stellar phase transition and RSG phases are presented in Sections 3, 4 and 5, respectively. We describe the grid of 2D simulations of bow shocks around massive stars, discuss their morphology, compare their substructures to an analytical solution for infinitely thin bow shock and present their luminosities and Hα surface brightnesses. Section 6 discusses our results. We conclude in Section 7.

### 2 Numerical Scheme and Initial Parameters

#### 2.1 Hydrodynamics, Boundary Conditions and Numerical Scheme

The governing equations are the Euler equations of classical hydrodynamics, including radiative cooling and heating for an optically thin plasma and taking into account electronic thermal conduction, which are

\[
\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{v}) = 0, \tag{1}
\]

\[
\frac{\partial \rho \mathbf{v}}{\partial t} + \nabla \cdot (\rho \mathbf{v} \otimes \mathbf{v}) + \nabla p = 0 \tag{2}
\]

and

\[
\frac{\partial E}{\partial t} + \nabla \cdot (E \mathbf{v}) + \nabla \cdot (p \mathbf{v}) = \Phi(T, \rho) + \nabla \cdot \mathbf{F}_c. \tag{3}
\]

In the system of equations (1)–(3), \( \mathbf{v} \) is the gas velocity in the frame of reference of the star, \( \rho \) is the gas mass density and \( p \) is its thermal...
pressure. The total number density \( n \) is defined by \( \rho = \mu m_\text{H} n \), where \( \mu \) is the mean molecular weight in units of the mass of the hydrogen atom \( m_\text{H} \). The total energy density is the sum of its thermal and kinetic parts,

\[
E = \frac{p}{(\gamma - 1)} + \frac{1}{2} \rho v^2,
\]

where \( \gamma \) is the ratio of specific heats for an ideal gas, i.e. \( \gamma = 5/3 \). The temperature inside a given layer of the bow shock is given by

\[
T = \frac{m_\text{H} p}{k_\text{B} \rho},
\]

where \( k_\text{B} \) is the Boltzmann constant. The quantity \( \Phi \) in the energy equation (3) gathers the rates \( \Lambda \) for optically thin radiative cooling and \( \Gamma_\text{w} \) for heating,

\[
\Phi(T, \rho) = n_\text{H}^2 \Gamma_\text{w}(T) - n_\text{H}^2 \Lambda(T),
\]

where the exponent \( \sigma \) depends on the ionization of the medium (see Section 2.4), and \( n_\text{H} \) is the hydrogen number density. The heat flux is symbolized by the vector \( \mathbf{F} \). The relation \( c_s = \sqrt{\gamma p/\rho} \) closes the system of partial differential equations (1)–(3), where \( c_s \) is the adiabatic speed of sound.

We perform calculations on a 2D rectangular computational domain in a cylindrical frame of reference \((O; R, z)\) of origin \( O \), imposing rotational symmetry about \( R = 0 \). We use a uniform grid divided into \( N_R \times N_z \) cells, and we pay attention to the number of cells resolving the layers of the bow shocks (Comerón & Kaper 1998). We choose the size of the computational domain such that the tail of the bow shock only crosses the downstream boundary \( z = z_{\text{max}} \). Following the methods of Comerón & Kaper (1998) and van Marle et al. (2006), a stellar wind is released into the domain by a half circle of radius 20 cells centred on the origin. We impose at every timestep a wind density \( \rho_w \propto r^{-2} \) on to this circle, where \( r \) is the distance to \( O \). We work in the frame of reference of the runaway star. Outflow boundary conditions are assigned at the \( z = z_{\text{max}} \) and \( R = R_{\text{max}} \) borders of the domain, whereas ISM material flows into the domain from the \( z = z_{\text{max}} \) border. The choice of a 2D cylindrical coordinate system possessing an intrinsic axisymmetric geometry limits us to the modelling of symmetric bow shocks only.

We solve the equations with the magnetohydrodynamics code \textsc{pluto} (Mignone et al. 2007, 2012). We use a finite volume method with the Harten–Lax–van Leer approximate Riemann solver for the fluid dynamics, controlled by the standard Courant–Friedrich–Levy parameter initially set to \( C_{\text{ CFL}} = 0.1 \). The equations are integrated with a second-order, unsplit, time-marching algorithm. This Godunov-type scheme is second-order accurate in space and in time. Optically thin radiative losses are linearly interpolated from tabulated cooling curves and the corresponding rate of change is subtracted from the pressure. The parabolic term in the equation (3), corresponding to the heat conduction is treated with the Super-Time-Stepping algorithm (Alexiades, Amiez & Gremaud 1996) in an operator-split, first-order accurate in time algorithm.

We use \textsc{pluto} 4.0 where linear interpolation in cylindrical coordinates is correctly performed by taking into account the geometrical centroids rather than the cell centre (Mignone 2014). We have found that this leads to better results compared to \textsc{pluto} 3.1, especially in close proximity to the axis. The diffusive solver chosen to carry out the simulations damps the dramatic numerical instabilities along the symmetry axis at the apex of the bow shocks (Vieser & Hensler 2007; Kwak, Henley & Shelton 2011) and is more robust for hypersonic flows. All the physical components of the model are included from the first timestep of the simulations.

**Figure 2.** Stellar evolutionary tracks used in the simulations. Thick solid red line, thin solid blue line and dashed orange line are the evolutionary tracks for our 10, 20 and 40 M\(_\odot\) models, respectively. Circles indicate the time of the beginning of the simulations for the MS phase and squares for the RSG phase.

### 2.2 Wind model

Stellar evolution models provide us with the wind parameters throughout the star’s life from the MS to the RSG phase (see evolutionary tracks in Fig. 2). We obtain the wind inflow boundary conditions from a grid of evolutionary models for non-rotating massive stars with solar metallicity (Brott et al. 2011). Their initial masses are \( M_\odot = 10, 20 \) and \( 40 \) M\(_\odot\) (the masses of the stars quoted hereafter are the zero-age main-sequence masses, unless otherwise stated), and they have been modelled with the Binary Evolution Code (Heger, Langer & Woosley 2000; Vink, de Koter & Lamers 2001) including mass-loss but ignoring overshooting. The mass-loss rate calculation includes the prescriptions for O-type stars by Vink, de Koter & Lamers (2000), Vink, de Koter & Lamers (2001) and for cool stars by de Jager, Nieuwenhuijzen & van der Hucht (1988).

Fig. 3 shows the stellar wind properties of the different models at a radius of \( r = 0.01 \) pc from the star. Mass-loss rate \( \dot{M} \), wind density \( \rho_w \) and velocity \( v_w \) are linked by

\[
\rho_w = \frac{\dot{M}}{4\pi r^2 v_w}.
\]

The wind terminal velocity is calculated from the escape velocity \( v_\text{esc} \) using \( v_w^2 = \beta_w(T)v_\text{esc}^2 \) (Eldridge et al. 2006), with \( \beta_w \) a parameter given in their table 1.

The mass-loss rate of the star has a constant value of around \( 10^{-9.5}, 10^{-7.3} \) and \( 10^{-6.2} \) M\(_\odot\) yr\(^{-1}\) during the MS phase of the 10, 20 and 40 M\(_\odot\) stars, respectively. After the transition to a RSG, the mass-loss increases to around \( 10^{-6.2} \) and around \( 10^{-5} \) M\(_\odot\) yr\(^{-1}\) for the 10 and 20 M\(_\odot\) stars, respectively. The evolutionary model of our 40 M\(_\odot\) star ends at the beginning of the helium ignition, i.e. it does not have an RSG phase (Brott, private communication). Such a star may evolve through the RSG phase but this is not included in our model (see panel f of Fig. 3). The wind velocity decreases by two orders of magnitude from \( \sim 1000 \) km s\(^{-1}\) during the MS phase to \( \sim 10 \) km s\(^{-1}\) for the RSG phase. The effective temperature of the star decreases from \( T_{\text{eff}} \sim 10^3 \) K during the MS phase to \( T_{\text{eff}} \sim 2.5-4.5 \times 10^4 \) K when the star becomes an RSG. The thermal pressure of the wind is proportional to \( T_{\text{eff}} \), according to the ideal gas equation of state. It scales as \( r^{-2\gamma} \) and is negligible during all
Bow shocks of Galactic, massive runaway stars

2.3 Interstellar medium

We consider homogeneous and laminar ISM with \( n_H = 0.57 \text{ cm}^{-3} \), which is typical of the warm neutral medium in the Galactic plane (Wolfire et al. 2003) from where most of runaway massive stars are ejected. The initial ISM gas velocity is set to \( v_{\text{ISM}} = -v_* \).

The photosphere of a MS star releases a large flux of hydrogen ionizing photons \( S_\star \), that depends on \( R_\star \) and \( T_{\text{eff}} \), which allows us to estimate \( S_\star = 10^{45} \text{ photon s}^{-1} \) \((T_{\text{eff}} \approx 2.52 \times 10^4 \text{ K})\), \( S_\star = 10^{48} \text{ photon s}^{-1} \) \((T_{\text{eff}} \approx 3.39 \times 10^4 \text{ K})\) and \( S_\star = 10^{49} \text{ photon s}^{-1} \) \((T_{\text{eff}} \approx 4.25 \times 10^4 \text{ K})\) for the 10, 20 and 40M\(_\odot\) stars, respectively (Diaz-Miller, Franco & Shore 1998). These fluxes produce a Strömgren sphere of radius,

\[
R_S = \left( \frac{3 S_\star}{4\pi n_\alpha B} \right)^{1/3}
\]

where \( \alpha_B \) is the case B recombination rate of H\(^+\), fitted from Hummer (1994). The Strömgren sphere is distorted by the bulk motion of the star in an egg-shaped H\(^+\) region (Raga 1986; Raga et al. 1997a; Mackey, Langer & Gvaramadze 2013). \( R_S \approx 4.3, 43 \) and 94 pc for the 10, 20 and 40M\(_\odot\) MS stars, respectively. \( R_S \) is larger than the typical scale of a stellar bow shock (i.e. larger than the full size of the computational domain of \( \sim \text{pc} \)). Because of this, we treated the plasma on the full simulation domain as photoionized with the corresponding dissipative processes (see panel a of Fig. 4), i.e. we neglect the possibility that a dense circumstellar structure could trap the stellar radiation field (Weaver et al. 1977).

We consider that both the wind and the ISM are fully ionized until the end of the MS, and we use an initial \( T_{\text{ISM}} \approx 8000 \text{ K} \) which is the equilibrium temperature of the photoionized cooling curve (see panel a of Fig. 4).

In the case of models without an ionizing radiation field, involving a phase transition or a RSG, the plasma is assumed to be in collisional ionization equilibrium (CIE). We adopt \( T_{\text{ISM}} \approx 3300 \text{ K} \), which corresponds to the equilibrium temperature of the photoionized cooling curve for the adopted ISM density (see panel b of Fig. 4).

2.4 Radiative losses and heating

A cooling curve for photoionized material has been implemented, whereas another assuming CIE is used for the gas that is not exposed to ionizing radiation. In terms of equation (6), we set \( \alpha = 2 \) for evolutionarily phases compared to the ram pressure of the wind in the free expanding region.

We run two simulations for each \( M_\star \) and for each considered space velocity \( v_* \): one for the MS and one for the RSG phase. Simulations are launched at 5 and 3 Myr of the MS phase for the 10 and 20M\(_\odot\) models, and at the zero-age main sequence for the 40M\(_\odot\) star, given its short lifetime (see the black circles in Figs 2 and 3). RSG simulations are started before the MS to RSG transition such that a steady state has been reached when the RSG wind begins to expand (see the black squares in Figs 2 and 3).

The wind material is traced using a scalar marker whose value \( Q \) obeys the linear advection equation,

\[
\frac{\partial (\rho Q)}{\partial t} + \nabla \cdot (\rho v Q) = 0
\]

This tracer is passively advected with the fluid, allowing us to distinguish between the wind and ISM material. Its value is set to \( Q(r) = 1 \) for the inflowing wind material and to \( Q(r) = 0 \) for the ISM material, where \( r \) is the vector position of a given cell of the simulation domain.

Figure 3. Physical parameters of the stellar winds used in our simulations. The top panels represent the wind velocity \( v_w \) (thick solid red line), the mass-loss rate \( \dot{M} \) (dashed orange line) and the wind number density \( n_w \) (thin solid blue line) during the MS phase of the 10, 20 and 40M\(_\odot\) stars, whereas the bottom panels show these parameters during the RSG phase of the same stars. Wind number density is calculated at 0.01 pc from the star and are proportional to the mass-loss rate \( \dot{M} \) (see equation 7). Black dots show the beginning of the simulations for the MS phase and black squares for the RSG phase (Table 1).
photoionized gases and $\alpha = 1$ for the CIE medium. The cooling component $\Lambda$ of equation (6) is

$$\Lambda = \Lambda_{\text{H}+\text{He}} + \Lambda_Z + \Lambda_{\text{RR}} + \Lambda_{\text{FL}},$$

(10)

where $\Lambda_{\text{H}+\text{He}}$ and $\Lambda_Z$ represent the cooling from hydrogen plus helium, and metals $Z$, respectively (Wiersma, Schaye & Smith 2009), for a medium with the solar helium abundance $n_{\text{He}} = n_{\text{He}}/n_{\text{H}} = 0.097$ (Asplund et al. 2009). $\Lambda_{\text{H}+\text{He}} + \Lambda_Z$ dominates the cooling at high $T$ (see panel a of Fig. 4). A cooling term for hydrogen recombination $\Lambda_{\text{RR}}$ is obtained by fitting the case B energy loss coefficient $\beta_B$ (Hummer 1994). The rate of change of $E$ is also affected by collisionally excited forbidden lines from elements heavier than helium, e.g. oxygen and carbon (Raga, Mellema & Lundqvist 1997b). The corresponding cooling term $\Lambda_{\text{FL}}$ is adapted from a fit of [O II] and [O III] lines (see equation A9 of Henney et al. 2009) with the abundance of $n_{\text{O}}/n_{\text{H}} = 4.89 \times 10^{-4}$ (Asplund et al. 2009).

The heating rate $\Gamma_2$ in equation (6) represents the effect of photons emitted by the hot stars ionizing the recombining H$^+$ ions and liberating energetic electrons. It is calculated as the energy of an ionizing photon after subtracting the ionization potential of a hydrogen atom, i.e. $5\text{eV}$ for a typical MS star (Oosterbroek & Bochkarev 1989), weighted by $\omega_{\text{H}}^\text{e}$.

At low temperatures ($T < 6 \times 10^4 \text{K}$), the cooling rate is the sum of all terms $\Lambda_{\text{H}+\text{He}} + \Lambda_Z + \Lambda_{\text{RR}}$ and $\Lambda_{\text{FL}}$, whereas for higher temperatures ($T > 6 \times 10^4 \text{K}$) only the ones for hydrogen, helium and $Z$ are used. The two parts of the curve are linearly interpolated in the range of $4.5 \times 10^3 < T < 6.0 \times 10^4 \text{K}$.

The CIE cooling curve (see panel b of Fig. 4) also assumes solar abundances (Wiersma et al. 2009) for hydrogen, helium and $Z$. The heating term $\Gamma_1$ represents the photoelectric heating of dust grains by the Galactic far-UV background. For $T \leq 1000 \text{K}$, we used equation C5 of Wolfire et al. (2003). We impose a low-temperature ($T < 1000 \text{K}$) electron number density profile $n_e$, using equation C3 of Wolfire et al. (2003). For $T > 1000 \text{K}$, we take the value of $n_e$ interpolated from the CIE curve by Wiersma et al. (2009).

A transition between the MS and the RSG phases requires a transition between photoionized and CIE medium. At the beginning of the RSG phase, our model ceases to consider the dissipation and heating for photoionized medium and adopts the ones assuming CIE medium. The assumption of CIE specifies $n_e/n_{\text{H}}$ as a function of $T$ (Wiersma et al. 2009). The mean mass per particle is calculated as

$$\mu(T) = \frac{1 + 4x_{\text{He}}}{(1 + x_{\text{He}})[1 + x(T)]},$$

(11)

where

$$x(T) = \left(\frac{n_{\text{He}}}{n_{\text{H}}}\right)_{T} / \left(\frac{n_{\text{He}}}{n_{\text{H}}}\right)_{T_{\text{max}}}$$

(12)

and $T_{\text{max}}$ is the upper limit of the cooling curve temperature range (Wiersma et al. 2009), and $x(T)$ is a quantity monotonically increasing with $T$, that gives the degree of ionization of the medium (see the top inset in Fig. 5). We then have an expression for $\mu$ with low and high $T$ limits of $\mu = 1.27$ and $0.61$ for neutral and fully ionized.
medium, respectively (e.g. Lequeux 2005). For simulations assuming CIE, we then obtain through $\mu(T)$ a one-to-one correspondence between $T/\mu \propto p/\rho$ (known) and $T$ (required) for each cell of the computational domain.

### 2.5 Thermal conduction

The circumstellar medium around runaway MS stars presents large temperature gradients across its shocks and discontinuities (e.g. $\Delta T \approx 10^3$ K at the reverse shock of the models for the 20 and 40 $M_\odot$ stars), which drive the heat flux (Spitzer 1962; Cowie & McKee 1977). Electrons move quickly enough to transfer energy to the adjacent low-temperature gas. The consequent equilibration of the pressure smooths the density profiles at the discontinuity between the wind and ISM material (Weaver et al. 1977).

Heat conduction is included in our models over the whole computational domain. For the models with partially neutral gas, e.g. during a phase transition or for models involving an RSG, $F_c$ is calculated at $T < 1000$ K with $n_e$ from equation C3 in Wolfire et al. (2003). Our study does not consider either the stellar or interstellar magnetic field, which make the heat conduction anisotropic (Orlando et al. 2008).

### 2.6 Relevant characteristic quantities of a stellar wind bow shock

A stellar wind bow shock generally has four distinct regions: the unperturbed ISM, the shocked ISM, the shocked wind material and the freely expanding wind. The shocked materials are separated by a contact discontinuity, the expanding wind from the star is separated from the shocked wind by the reverse shock and the structure’s outermost border is marked by the forward shock (e.g. van Buren 1993).

The stand-off distance of the bow shock is

$$R(0) = \sqrt{\frac{M v_w}{4\pi \rho_{\text{ISM}} v^2}}$$

(13)

where $\theta$ is the angle from the direction of motion in degrees and $R(0)$ is given by equation (13).

The dynamical time-scale of a layer constituting a stellar wind bow shock is equal to the time a fluid element spends in it before it is advected downstream,

$$t_{\text{dyn}} = \frac{\Delta z}{v}$$

(15)

where $\Delta z$ is the thickness of the layer along the $Oz$ direction and $v$ is a characteristic velocity of the gas in the considered region, i.e. the post-shock velocity $v \approx v_w/4$ in the shocked wind or $v \approx v_*/4$ in the shocked ISM. The gas density and pressure govern the cooling time-scale,

$$t_{\text{cool}} = \frac{\rho}{\dot{E}} \equiv \frac{p}{(\gamma - 1)\Lambda(T)\rho^2}$$

(16)

These two time-scales determine whether a shock is adiabatic ($t_{\text{dyn}} \ll t_{\text{cool}}$) or radiative ($t_{\text{dyn}} \gg t_{\text{cool}}$).

### 2.7 Presentation of the simulations

The parameters used in our simulations are gathered together with information concerning the size of the computational domain in Table 1. The size of the computational domain is inspired by Comerón & Kaper (1998), i.e. we use a sufficient number of cells $N_R$ to adequately resolve the substructures of each bow shock in the direction of the stellar motion. As $v_*$ increases, the bow shock and the domain size decreases, so the spatial resolution $\Delta = R_{\text{max}}/N_R$ also decreases. The dimensions of the domain are chosen such that the tail of the bow shock only crosses the $z = z_{\text{min}}$ boundary, but never intercepts the outer radial border at $R = R_{\text{max}}$ to avoid numerical boundary effects.

We model bow shocks for a space velocity $20 \leq v_* \leq 70$ km s$^{-1}$, since these include the most probable space velocities of runaway stars (Baranov et al. 1971). The analytical approximation for the shape of an infinitely thin bow shock is

$$R(\theta) = R(0)\csc \left( \frac{\pi}{180} \right) \sqrt{\frac{3}{1 - \theta} \left( 1 - \frac{\pi}{180} \right) \cot \left( \frac{\pi}{180} \right)}.$$  

We calculated the analytical approximation for the shape of an infinitely thin bow shock.

Figure 6. Grid of stellar wind bow shocks from the MS phase of the $10\,\text{M}_\odot$ initial mass star as a function of the space velocity with respect to the ISM, with 20 km s$^{-1}$ (top panel), 40 km s$^{-1}$ (middle panel) and 70 km s$^{-1}$ (bottom panel). The nomenclature of the models follows Table 1. The gas number density is shown with a density range from $10^{-21}$ to $5.0$ cm$^{-3}$ in the logarithmic scale. The solid black contour traces the boundary between wind and ISM material. The $x$-axis represents the radial direction and the $y$-axis the direction of stellar motion (in pc). Only part of the computational domain is shown.

The theory of Baranov et al. (1971) predicts that $R(0) \propto v_{\ast}^{-1}$ and $R(0) \propto M^{1/2}$ because the stand-off distance depends on the balance between the wind ram pressure with the ISM ram pressure. The size of the bow shock decreases as a function of $v_{\ast}$; $R(0)$ decreases by a factor of 2 if $v_{\ast}$ doubles, e.g. $R(0) \approx 0.13$ in model MS1020 but $R(0) \approx 0.06$ in model MS1040 (see the upper and middle panels of Fig. 6). The bow shocks also scale in size with $\dot{M}$, e.g. at fixed $v_{\ast}$ its size for the 10 $\text{M}_\odot$ star is smaller by a factor of 10 compared to the size of the bow shock from the 20 $\text{M}_\odot$ star, which in turn is smaller by a factor of $\approx 3.5$ compared to one from the 40 $\text{M}_\odot$ star (e.g. see the middle panels of Figs 6–8). If we look again at $\dot{M}$ in Fig. 3 (a–c), we find $\dot{M} \approx 10^{-9.5}$, $\approx 10^{-7.3}$ and $\approx 10^{-6}$ $\text{M}_\odot$ yr$^{-1}$ for the 10, 20 and 40 $\text{M}_\odot$ star, respectively. We see that these sizes are in accordance with the theory and arise directly as a result of equation (13).
Figure 8. As Fig. 6, with an initial stellar mass of 40 \( M_{\odot} \).

Table 2. Bow shock morphological properties at the contact discontinuity. The parameter \( R(0) \) (in pc) is the stand-off distance of the bow shock at the contact discontinuity and \( R(0)/R(90) \) is the ratio plotted in Fig. 9, with \( R(90) \) the radius perpendicular to the direction of motion.

Figure 9. Comparison between the ratio \( R(0)/R(90) \) for the MS and supergiant models with the theoretical value of \( 1/\sqrt{3} \approx 0.58 \) predicted by Wilkin (1996, horizontal dotted blue line). We distinguish between the contact discontinuity (red crosses) and the forward shock (orange dots) of each model.

The relative thickness of the substructures varies with the wind and ISM properties because the gas velocity determines both the post-shock temperature, i.e. governs the cooling physics at the reverse shock and in the shell, and the compression of the shocked ISM. Our simulations with \( v_r = 20 \text{ km s}^{-1} \) have weak forward shocks, i.e. compression at the forward shock is not important. The thickness of the layer of shocked ISM gas with respect to \( R(0) \) is roughly independent of \( M_\star \) for these models (see the upper panels of Figs 6–8). The shocked ISM density increases for models with \( v_r \geq 40 \text{ km s}^{-1} \) because the high post-shock temperature makes the cooling efficient. The variations of \( \dot{M} \) at a given \( v_r \) modify the morphology of the bow shock because a stronger wind ram pressure enlarges the size of the bow shock and makes the shell thinner with regard to \( R(0) \) (see models MS1020 and MS4020 in the upper panels of Figs 6 and 8).

Our simulations with \( v_r = 20 \text{ km s}^{-1} \) all have a stable density field (see the upper panels of Figs 6–8). The simulations with \( v_r = 40 \text{ km s}^{-1} \) are bow shocks with radiative forward shocks (i.e. with a dense and thin layer of shocked ISM). Our simulations for \( M_\star \geq 20 M_\odot \) and with \( v_r = 70 \text{ km s}^{-1} \) show instabilities at both the contact and the material discontinuity, see the middle panel of Figs 7 and 8. Our models for the 40 M\(_\odot\) star with \( v_r \geq 40 \text{ km s}^{-1} \) are similar. Model MS4040 is slightly more unstable than model MS2070 whereas model MS4070 shows even stronger instability which develops at its forward shock and dramatically distorts its dense and thin shell, as shown in the bottom panel of Fig. 8. The large density gradient across the material discontinuity allows Rayleigh–Taylor instabilities to develop. The entire shell of cold ISM gas has distortions characteristic of the non-linear thin-shell instability (Vishniac 1994; Garcia-Segura, Mac Low & Langer 1996).

3.2 Comparison of the models with the analytical solution

In Fig. 9, we compare \( R(0)/R(90) \) with the analytical solution for a bow shock with a thin shell (\( R(0)/R(90) \approx 1/\sqrt{3} \approx 0.58 \); Wilkin 1996). \( R(0)/R(90) \) at the contact discontinuity decreases as a function of \( v_r \), e.g. models MS2020 and MS2070 have \( R(0)/R(90) \approx 0.59 \) and \( \approx 0.56 \), respectively. \( R(0)/R(90) \) at the forward shock increases with \( v_r \) and \( \dot{M} \) (see Figs 6–8). The contact discontinuity is the appropriate measure to match the analytical solution.
3.3 Thermal conduction

Fig. 11 illustrates the effects of heat conduction on the shape of a bow shock. Panel (a) shows the density field of model MS2040, and panel (b) shows the same model but without thermal conduction. The dashed contour traces the border between wind and ISM gas. The streamlines show the penetration of ISM material into the hot bubble. The bow shock including thermal conduction is larger by a factor ≈1.4 in both the directions normal and parallel to the direction of motion. Its shell is denser and splits into two layers of hot and cold shocked ISM, whereas the model without thermal conduction has a single and less compressed region of ISM material.

The position of the reverse shock is insensitive to thermal conduction because heat lost at the material discontinuity is counterbalanced by the large wind ram pressure (see panels a and b of Fig. 11). Fig. 12 illustrates that the shocked regions of a bow shock with heat conduction have smooth density profiles around the contact discontinuity (see panels a and c of Fig. 12). This is consistent with previous models of a steady star (see fig. 3 of Weaver et al. 1977) and of moving stars (see fig. 7 of Comerón & Kaper 1998). Electrons carry internal energy from the hot shocked wind to the shocked ISM, e.g. the 10M⊙ models have a temperature jump amplitude of ΔT ≈ 107 K across the contact discontinuity.

Our simulation of model MS1040 (see Fig. 6) provides us with the parameters of the hot bubble (T ≈ 107 K, n ≈ 0.02 cm−3) and the shell (T ≈ 105 K, n ≈ 3.3 cm−3). The shocked ISM gas has a velocity v ≈ 25 km s−1 and μ = 0.61. Using equation (15) and (16), we find that the hot gas in the inner (tcool ≈ 1.11 × 107 ≫ tcond ≈ 1.4 × 104 Myr) and outer (tcool ≈ 2.94 × 108 > tcond ≈ 1.0 × 107 Myr) layers of the bow shock are adiabatic and slightly radiative, respectively. The radiative character of the shell is more pronounced for models with v > 40 km s−1. Note that the hot bubble never cools, i.e. tcool refers here to the time-scale of the losses of internal energy by optically thin radiative processes, which are compensated by the conversion of kinetic energy to heat at the reverse shock. The thermal conduction time-scale is

$$t_{\text{cond}} = \frac{7πl^2}{2(γ − 1)\kappa(T)T^3},$$

where κ(T) is the heat conduction coefficient and l a characteristic length along which heat transfer happens (Orlando et al. 2010).
Because $\epsilon(T) \propto T^{5/2}$ (Cowie & McKee 1977), $t_{\text{cond}} \propto T^{-7/2}$, i.e. heat conduction is a fast process in a hot medium. Consequently, we have $t_{\text{dyn}}/t_{\text{cond}} \approx 1.46 \times 10^{5} \gg 1$ and $t_{\text{cool}}/t_{\text{cond}} \approx 1.16 \times 10^{10} \gg 1$ in the hot bubble ($l = 0.035$ pc) whereas we find $t_{\text{gas}}/t_{\text{cond}} \approx 1.71 \times 10^{5} \ll 1$ and $t_{\text{cool}}/t_{\text{cond}} \approx 5.03 \times 10^{5} \ll 1$ in the shell ($l = 0.025$ pc) of the model MS1040, which explains the differences between the models shown in Fig. 11. All of our simulations of the MS phase behave similarly because their hot shocked wind layers have similar temperatures. Heat transfer across the bubble is always faster than the dynamical time-scale of the gas.

As a consequence, the pressure increases in the shocked ISM, pushing both the contact discontinuity inwards and the forward shock outwards. The region of shocked wind conserves its mass but loses much of its pressure. To balance the external pressure, its volume decreases and the gas becomes denser. Two concentric substructures of shocked ISM form: an inner one with high temperature and low density adjoining the material discontinuity, and an outer one with low temperature and high density. Previous investigations about the effects of heat conduction inside circumstellar nebulae around runaway hot stars are available in section 4.6 of Comerón & Kaper (1998).

### 3.4 Bow shock emissivity

#### 3.4.1 Luminosities

The bow shock luminosities of all our models are plotted in the panel (a) of Fig. 13. It shows the emitted light as a function of mass-loss $M$ and space velocity $v_{s}$ (i.e. by model). $L_{\text{gas}}$ is the bow shock luminosity from optically thin cooling of the gas and the part of this which originates from the wind material is designated as $L_{\text{wind}}$. The bow shock luminosities are calculated taking into account the cylindrical symmetry of the models by integrating the radiated energy in the $z \geq 0$ region (Mohamed et al. 2012). The optically thin gas radiation is therefore computed as

$$L_{\text{gas}} = 2\pi \int_{\Delta} L_{\alpha} n_{\alpha} R_{\Delta} RdRdz,$$

where $\Delta$ represents the considered volume. The heating terms are estimated with a similar method, as

$$\tilde{\Gamma}_{\alpha} = 2\pi \int_{\Delta} \Gamma_{\alpha} n_{\alpha} R_{\Delta} RdRdz,$$

where $\tilde{\Gamma}_{\alpha=1}$ is the heating rate per unit volume for UV heating of grains, and $\tilde{\Gamma}_{\alpha=2}$ is the heating rate per unit volume square for photoionization heating. Inserting the quantities $Q(r)$ or $1 - Q(r)$ in the integrant of equation (18) or (19) allows us to separate the contributions from wind and ISM material. The panels of Fig. 13 also specify the luminosity from Hα emission $L_{\text{H}\alpha}$ (calculated using the prescriptions by Osterbrock & Bechkarov 1989; our Appendix A) and the infrared luminosity of reprocessed starlight by dust grains $L_{\text{IR}}$ (calculated treating the dust as in Mackey et al. 2012; our Appendix B). None the less, $L_{\text{IR}}$ does not contribute to the thermal physics of the plasma and is not included in the calculations of either $L_{\text{gas}}$ or $L_{\text{wind}}$. The luminosities $L_{\text{gas}}$, $L_{\text{wind}}$, $L_{\text{H}\alpha}$, $L_{\text{IR}}$, the heating rates $\tilde{\Gamma}_{\alpha}$ and the stellar luminosity $L_{\star}$, provided by the stellar evolution models (Brott et al. 2011), are detailed in Table 3.

The bow shock luminosity of optically thin gas $L_{\text{gas}}$ decreases by an order of magnitude between the models with $v_{s} = 20$–70 km s$^{-1}$, but increases by several orders of magnitude with $M$, e.g. $L_{\text{gas}} \approx 1.4 \times 10^{13}$ and $\approx 3.9 \times 10^{15}$ erg s$^{-1}$ for the models MS1020 and MS4020, respectively. $L_{\text{gas}}$ is influenced by (i) $v_{s}$ which governs the compression factor of the shell, and (ii) by the size of the bow shock which increases with $M$ and decreases with $v_{s}$. Moreover, we find that emission by optically thin cooling is principally caused by optical forbidden lines such as $\text{[O II]}$ and $\text{[O III]}$ which is included in the cooling curve in the range $\approx 8000 \leq T \leq 6.0 \times 10^{4}$ K (see estimate of the luminosity $L_{\text{IR}}$ produced by optical forbidden lines in Table 3).

The contribution of optically thin emission from stellar wind material, $L_{\text{wind}}$, to the total luminosity of optically thin gas radiation is negligible e.g. $L_{\text{wind}}/L_{\text{gas}} \approx 10^{-6}$ for model MS2020. The variations of $L_{\text{wind}}$ roughly follows the variations of $L_{\text{gas}}$. The volume occupied by the shocked wind material is reduced by heat transfer (see the black contours in Figs 6–8) and this prevents $L_{\text{wind}}$ from becoming important relative to $L_{\text{gas}}$. It implies that most of the emission by radiative cooling comes from shocked ISM gas which cools as the gas is advected from the forward shock to the contact discontinuity. $L_{\text{H}\alpha}$ is smaller than $L_{\text{gas}}$ by about 1–3 orders of magnitude and larger than $L_{\text{wind}}$ by 2–5 orders of magnitude, e.g. model MS2040 has $L_{\text{H}\alpha}/L_{\text{gas}} \approx 10^{-1}$ and $L_{\text{H}\alpha}/L_{\text{wind}} \approx 10^{5}$. The Hα emission therefore mainly comes from ISM material. More precisely, we suggest that $L_{\text{H}\alpha}$ originates from the cold innermost shocked ISM since the
Hα emissivity \( \propto T^{-0.9} \) (our Appendix A). The variations of \( L_{\text{H}\alpha} \) follow the global variations of \( L_{\text{gas}} \), i.e. the H\( \alpha \) emission is fainter at high \( v_z \), e.g. \( L_{\text{H}\alpha} \approx 1.3 \times 10^{38} \) and \( \approx 2.6 \times 10^{38} \ \text{erg s}^{-1} \) for models MS2020 and MS2070, respectively. The gap between \( L_{\text{gas}} \) and \( L_{\text{H}\alpha} \) increases with \( v_z \), because the luminosities are calculated for \( z > 0 \) whereas the H\( \alpha \) maximum is displaced to \( z < 0 \) as \( v_z \) increases (see further discussion in Section 3.4.2).

\( L_{\text{IR}} \) is larger than \( L_{\text{gas}} \) by about 1–3 orders of magnitude in all our simulations. We find that \( L_{\text{IR}} \gg L_{\text{H}\alpha} \), with a gap in various \( v_z \) at a considered \( M \), e.g. \( L_{\text{IR}}/L_{\text{H}\alpha} \approx 10^2 \) and \( \approx 10^3 \) for models MS2020 and MS2070, respectively. These large \( L_{\text{IR}} \) suggest that bow shocks around MS stars should be much more easily observed in the infrared than at optical wavelength. We draw further conclusions on the detectability of bow shocks generated by runaway MS stars moving through the Galactic plane in Section 6.2.

### 3.4.2 Synthetic emission maps

Figs 14–16 show synthetic H\( \alpha \) emission maps of the bow shocks (left) together with dust surface mass density maps (right), from the slowest (\( v_z = 20 \ \text{km s}^{-1} \), top panels) to the highest (\( v_z = 70 \ \text{km s}^{-1} \), bottom panels) models, respectively. These maps take into account the rotational symmetry of the coordinate system (our Appendix A). The ISM background is ignored, i.e. we set its density to zero in the computation of the projected emissivity and dust density, so that the surface brightness and the surface mass density only refer to the bow shocks. The dust surface density is calculated by projecting the shocked ISM gas weight by a gas-to-dust ratio (our Appendix B), i.e. we considered that the wind material of a star is dust free during the MS.

The region of maximum H\( \alpha \) surface brightness is located at the apex of the bow shocks in the simulations with \( v_z = 20 \ \text{km s}^{-1} \) and extends or displaces to its tail (i.e. \( z < 0 \)) as \( v_z \) increases. As the ISM gas enters a bow shock generated by an MS star, its density increases and the material is heated by thermal conduction towards the contact discontinuity, so its H\( \alpha \) emissivity decreases (see panels a and c of Fig. 12). The competition between temperature increase and gas compression produces the maximum emissivity at the contact discontinuity which separates hot and cold shocked ISM gas. The reverse shock and the hot bubble are not seen because of both their low density and their high post-shock temperature. Simulations with \( v_z \approx 40 \ \text{km s}^{-1} \) have their peak emissivity in the tail of the bow shock because the gas does not have time to cool at the apex before it is advected downstream. Simulations with high \( v_z \) and strong \( M \) (e.g. model MS4070) have bow shocks shining in H\( \alpha \) all along their contact discontinuity, i.e. the behaviour of the H\( \alpha \) emissivity with respect to the large compression factor in the shell \( \propto n^2 \) overwhelms that of the post-shock temperature \( \propto T^{-0.9} \).

The dust surface mass density increases towards the contact discontinuity (see the left-hand panels of Figs 14–16). Panel (a) of Fig. 17 shows that normalized cross-sections of both the H\( \alpha \) surface brightness and the dust surface mass density of model MS2040, taken along the direction of motion of the star in the \( z \equiv 0 \) region of the bow shock, peak at the same distance from the star. We find a similar behaviour for all our bow shock models of hot stars. This suggests that both maximum H\( \alpha \) and infrared emission originate from the same region, i.e. near the contact discontinuity in the cold region of shocked ISM material constituting the outermost part of a bow shock generated by an MS star.

The maximum H\( \alpha \) surface brightness of the brightest models (e.g. model MS2020) is \( \geq 6 \times 10^{-17} \ \text{erg s}^{-1} \ \text{cm}^{-2} \ \text{arcsec}^{-2} \), which is above the diffuse emission sensitivity limit of the SuperCOSMOS H\( \alpha \)-alpha Survey (SHS: Parker et al. 2005) of 1.1–2.8 \( \times 10^{-17} \ \text{erg s}^{-1} \ \text{cm}^{-2} \ \text{arcsec}^{-2} \) and could therefore be observed. The bow shocks around a central star less massive than 20 M\( \odot \) are fainter and could be screened by the H\( \alpha \) region generated by their driving star. This could explain why we do not see many stellar wind bow shocks around massive stars in H\( \alpha \).

### 4 THE STELLAR PHASE TRANSITION

In Fig. 18, we show the gas density field in our bow shock model of our initially 20 M\( \odot \) star moving with velocity \( v_z = 40 \ \text{km s}^{-1} \) during the stellar phase transition from the MS phase (top panel) to the RSG phase (bottom panel). The figures correspond to times 3.400, 8.208, 8.430, 8.468 and 8.500 Myr, respectively.
Figure 14. The figures show the Hα surface brightness (left, in erg s⁻¹ cm⁻² arcsec⁻²) and the dust surface mass density (right, in g cm⁻²) for the bow shocks from the MS phase of our 10 M☉ initial mass star. Quantities are calculated excluding the undisturbed ISM and plotted in the linear scale, as a function of the considered space velocities. The x-axis represents the radial direction and the y-axis the direction of stellar motion (in pc). Only part of the computational domain is shown.

Panel (a) of Fig. 18 shows the density field of the circumstellar medium during the MS phase of our star (as in the middle panel of Fig. 7). When the MS phase ends, both the stellar mass-loss rate \( \dot{M} \) and wind density \( n_w \) increase by more than an order of magnitude (see panel e of Fig. 3) so that the bow shock inflates and its stand-off distance doubles to reach about 1.7 pc (see panel b of Fig. 18). At about 8.350 Myr, the wind velocity decreases rapidly and a shell of dense and slow RSG wind develops inside the bow shock from the MS phase (see panel c of Fig. 18). A double-arced structure forms at its apsis, as shown in the study detailing a model of Betelgeuse returning to the RSG phase after undergoing a blue loop (Mackey et al. 2012). Under the influence of the stellar motion, the colliding shells expand beyond the forward shock of the MS bow shock and penetrate into the undisturbed ISM. The former bow shock recedes downwards from the direction of stellar motion because it is not supported by the ram pressure of the hot gas, whereas the new-born RSG bow shock adjusts itself to the changes in the wind parameters and a new contact discontinuity is established (see panel d of Fig. 18). After the phase transition, only the bow shock from the RSG phase remains in the domain (see panel e of Fig. 18).

As the star leaves the MS phase, the modifications of its wind properties affect the strengths of its termination and forward shocks. The decelerating wind slows the gas velocity by about two orders of magnitude in the post-shock region at the reverse shock. The hot bubble cools rapidly (\( t_{\text{cool}} \ll t_{\text{dyn}} \ll t_{\text{cond}} \)) while the region of shocked wind becomes thicker and denser (see panels c–d of Fig. 3). The transfer of thermal energy by heat conduction ceases because there is no longer a sharp temperature change \( \Delta T \geq 10^7 \) K across the contact discontinuity. Consequently, the position of the material discontinuity migrates from near the reverse shock to be coincident with the contact discontinuity (see the solid black line in panels a–c of Fig. 18). It sets up a dense and cold bow shock whose layer of shocked wind is thicker than the outer region of ISM gas (see panel d of Fig. 18).

The above described young bow shock of our initially 20 M☉ star is typical of the circumstellar medium of a runaway star undergoing a transition from a hot to a cold evolutionary phase. The phase transition time-scale is longer for small \( v_\star \) and shorter for high \( v_\star \). The bow shocks generated by lower mass stars, e.g. our initially 10 M☉ star may be more difficult to observe because of their smaller and fainter shells. The wind parameters of our initially 10 M☉ star change more abruptly (\( \sim 10^4 \) yr, see panels a and d of Fig. 3), i.e. the preliminary increase of \( \dot{M} \) and \( n_w \) is quicker and the subsequent inflation of their bow shock is much less pronounced. The slightly inflated bow shock from the MS phase has no time to reach a steady state before the transition happens (as in panel b of Fig. 18). Our slowly moving star with velocity 20 km s⁻¹ (i.e. the model RSG2020) has a supergiant phase that is shorter than the
advection time of the hot bow shock, i.e. the former bow shock has not progressed downstream when the star ends its life (Section 5).

Our stellar phase transitions last $10^4 - 10^5$ yr, i.e. they are much shorter than both the MS and the RSG phases (see Fig. 3). This makes the direct observation of interacting bow shocks of stars in the field a rare event. Changes in the ambient medium can also affect the properties of bow shocks and wind bubbles, e.g. the so-called Napoleon’s hat which surrounds the remnant of the supernova SN1987A (Wampler et al. 1990; Wang & Wampler 1992) and highlights the recent blue loop of its progenitor (Wang et al. 1993).

5 THE RSG PHASE

5.1 Physical characteristics of the bow shocks

We show the gas density field in our bow shock models of the RSG phase RSG1020 ($M_{\odot}$ initial stellar mass, $v_*=20\,\text{km\,s}^{-1}$, upper panel), RSG1040 ($10\,M_{\odot}, 40\,\text{km\,s}^{-1}$, middle panel) and RSG1070 ($10\,M_{\odot} , 70\,\text{km\,s}^{-1}$, lower panel) in Fig. 19. Fig. 20 is similar for the $20\,M_{\odot}$ initial mass star. Figs 19 and 20 show the contour $Q(r) = 1/2$ which traces the discontinuity between the wind and the ISM gas. $R(0)$ and $R(0)/R(90)$ are summarized for each panel in Table 2. The simulations were run until at least 40 $t_{\text{cmsg}}$ after the stellar phase transition, i.e. after the abrupt increase of $M$ accompanied by a steep decrease of $v_\infty$ (see panels d-f of Fig. 3).

The size of the bow shocks is predicted to scale as $\dot{M}^{1/2}, v_\infty^{1/2}$ and $v_*^{-1}$ according to equation (13) and Baranov et al. (1971). The scaling between simulations with $v_* = 40$ and $70\,\text{km\,s}^{-1}$ follows the prediction well, but deviations occur in the $v_* = 20\,\text{km\,s}^{-1}$ simulations (see Table 2). The most deviating simulations either have a very weak shock preventing the forward shock from cooling and forming a thin shell (e.g. model RSG1020), or have not reached a steady state after the phase transition and consist of two interacting bow shocks (e.g. model RSG2020).

The thickness of the shocked layers depends on the cooling physics of the gas. Our simulations with $v_* = 20 \, \text{km\,s}^{-1}$ have a roughly constant density across the material discontinuity. The reverse and forward shocks are weak without much heating and both layers can cool to about the same temperature. In models with $v_* = 40 \, \text{km\,s}^{-1}$, the post-shock temperature at the forward shock is larger than for $v_* = 20 \, \text{km\,s}^{-1}$ and rapid cooling to $T \approx 10^4 \, \text{K}$ leads to a stronger compression of the material (see panel b and d of Fig. 12). At $v_* = 70 \, \text{km\,s}^{-1}$, the shocked ISM is a thin layer that has much lower density than the shocked wind (e.g. models RSG1070 and RSG2070). The forward shock is strong; therefore, the hot shocked ISM has insufficient time to cool before it is advected downstream.

Our model RSG1020 with the weakest shocks is stable. Model RSG2020 has an expanding RSG wind that is replacing the previous MS shell. This simulation still has the remainder of the MS wind bow shock interacting with the bow shock from the RSG wind at the conditions.
end of the star life. The contact discontinuity of the supergiant shell shows Rayleigh–Taylor fingers because of the density gradient between the old and new bow shocks. Our models with $v_\ast \geq 40 \, \text{km} \, \text{s}^{-1}$ have $v_m \ll v_\ast$ and so their bow shocks develop instabilities which distort dense and thin shells (Dgani et al. 1996a). The density field of the model RSG2070 resembles an isothermal bow shock with a distortion of the forward shock typical of the non-linear thin-shell and transverse-acceleration instabilities (Blondin & Koerwer 1998). This instability arises because $R(0)$ is much larger than the cooling length in the shocked ISM and shocked wind.

$R(0)/R(90)$ decreases at the contact discontinuity as a function of $v_\ast$, e.g. $R(0)/R(90) \approx 0.6$ and $\approx 0.58$ for models RSG2020 and RSG2070, respectively. $R(0)/R(90)$ at the forward shock increases with $v_\ast$ and $M$, e.g. model RSG2020 and RSG2070 have $R(0)/R(90) \approx 0.46$ and $\approx 0.59$, respectively. These measures do not perfectly satisfy Wilkin’s solution, except for the models with $v_\ast = 70 \, \text{km} \, \text{s}^{-1}$, although the ratios for the contact discontinuity are all within 10 per cent of the analytic solution. Only the $v_\ast = 70 \, \text{km} \, \text{s}^{-1}$ simulations, with their thin bow shocks that come closest to the isothermal limit, have forward shocks that satisfy $R(0)/R(90) \approx 1/\sqrt{3}$ (see Fig. 20).

Because the temperature jumps are small across the interfaces and shocks in the bow shocks around RSG, e.g. $\Delta T \approx 10^3 \, \text{K}$ at the reverse shock and $\Delta T \approx 4 \times 10^4 \, \text{K}$ at the forward shock of model RSG1040, thermal conduction is not important. The bow shocks around RSG therefore have coincident contact and material discontinuities (see the black contours in Figs 21 and 22).

5.2 Bow shock emissivity

5.2.1 Luminosities

The luminosities $L_{\text{gas}}$, $L_{\text{wind}}$, $L_{\text{H}\alpha}$ and $L_{\text{IR}}$ of the bow shocks generated by our RSG models are plotted as a function of $M$ and $v_\ast$ in panel (b) of Fig. 13. As is the case for bow shocks produced by MS stars, $L_{\text{gas}}$ is influenced by $v_\ast$ and by the size of the bow shock. $L_{\text{gas}} \propto n^2$ and slightly increases with $v_\ast$ because the compression factor of the shell is larger for high $v_\ast$. The variations in size drive the increase of $L_{\text{gas}}$ as a function of $M$ if $v_\ast$ is fixed. In contrast to the bow shocks around MS stars, the increase of $L_{\text{gas}}$ seen in panel (b) of Fig. 13 for a given model triplet shows that the luminosity is more influenced by the density than by the volume of the bow shocks.

$L_{\text{wind}}$ is several orders of magnitude dimmer than $L_{\text{gas}}$, e.g. $L_{\text{wind}}/L_{\text{gas}} \approx 10^{-2}$ for model RSG1040, i.e. the wind contribution is negligible compared to the luminosity of the shocked ISM gas. The difference between $L_{\text{wind}}$ and $L_{\text{gas}}$ is less than in our MS models because the gas cooling behind the slow RSG reverse shock is efficient. Model RSG1020 behaves differently because even though it scales in volume with model RSG1040, its small $v_\ast$ results in a weak
Figure 17. Normalized cross-sections taken along the direction of motion of the star, through the H\textalpha surface brightness and the dust surface mass density of the bow shock models MS2040 (a) and RSG1040 (b).

forward shock which is cool so there is little cooling in the shocked ISM ($L_{\text{wind}} \sim L_{\text{gas}}$). The total bow shock luminosity of optically thin radiation of model RSG2020 is increased by a contribution from the former MS bow shock around the forming RSG shell (see the upper panel of Fig. 20).

The bow shock luminosity of H\textalpha emission is negligible compared to the total bow shock luminosity, e.g. $L_{\text{H}\alpha}/L_{\text{gas}} \approx 10^{-3} - 10^{-5}$, see the lower panel of Fig. 13. $L_{\text{H}\alpha}$ increases with $v_*$, e.g. $L_{\text{H}\alpha} \approx 7.1 \times 10^{29}$ and $\approx 1.7 \times 10^{30}$ erg s$^{-1}$ for model RSG2040 and RSG2070, respectively. The H\textalpha emission of the bow shocks for the 10 and 20 $M_\odot$ stars differs by $\approx 1$ order of magnitude. Models RSG1020 and RSG2020 have little H\textalpha emission because their weak forward shocks do not ionize the gas significantly and prevent the formation of a dense shell.

The infrared luminosity is such that $L_{\text{IR}} \gg L_{\text{gas}}$. This is because of the fact that $L_{\text{IR}}$ provides an upper limit for the infrared light (our Appendix B) and because the circumstellar medium around RSG is denser than that during the MS phase, i.e. there is a lot of dust from the stellar wind in these bow shocks that can reprocess the stellar radiation. $L_{\text{IR}}$ increases by about two orders of magnitude between the 10 and 20 $M_\odot$ models if $v_*$ is considered fixed, which is explained by their different wind and bow shock densities (see Figs 19 and 20). Model RSG2020 does not fit this trend because the huge mass of the bow shock of the previous evolutionary phase affects its luminosity $L_{\text{IR}} \approx 1.3 \times 10^{39}$ erg s$^{-1}$. The enormous infrared luminosity of bow shocks around RSG compared to their optically

Figure 18. Time sequence of the stellar phase transition of the initially 20$M_\odot$ star moving with 40 km s$^{-1}$. The figures show the transition from the MS phase (top panel) to the RSG phase (bottom panel) of the star. The gas number density is shown with a density range from $10^{-3}$ to 5.0 cm$^{-3}$ in the logarithmic scale. The solid black contour traces the boundary between wind and ISM material $Q(r) = 1/2$. The $x$-axis represents the radial direction and the $y$-axis the direction of stellar motion (in pc).
Bow shocks of Galactic, massive runaway stars

Figure 19. Grid of stellar wind bow shocks from the RSG phase of the 10 $M_\odot$ initial mass star according to the space velocity with respect to the ISM, with 20 km s$^{-1}$ (top panel), 40 km s$^{-1}$ (middle panel) and 70 km s$^{-1}$ (bottom panel). Models nomenclature follows Table 1. Gas number density is shown with a density range from 0.1 to 30.0 cm$^{-3}$ in the logarithmic scale. Note that the colour scale is upset compared to Figs 6–8. The solid black contours trace the boundary between wind and ISM, $Q(r) = 1/2$. The x-axis represents the radial direction and the y-axis the direction of stellar motion (in pc). Only part of the computational domain is shown.

thin gas radiation suggests that they should be more easily observed in the infrared than in the optical bands and partly explains why the bow shock around Betelgeuse was discovered in the infrared.

5.2.2 Synthetic emission maps

Figs 21 and 22 show the bow shock H$\alpha$ surface brightness (left-hand panels) and dust surface mass density (right-hand panels) for our 10 and 20 $M_\odot$ models, respectively. Each figure shows $v_*=20$ km s$^{-1}$ (top), $v_*=40$ km s$^{-1}$ (middle) and $v_*=70$ km s$^{-1}$ (bottom). For RSG, we assume that both the stellar wind and the ISM gas include dust (our Appendix B).

In our models the H$\alpha$ emission of bow shocks produced by RSG originates from the shocked ISM in the post-shock region at the forward shock. The region of maximum emission is at the apex of the structure for simulations with $v_* = 20$ km s$^{-1}$ and is extended to the tail as $v_*$ increases, e.g. for the model RSG1040. The surface brightness increases with $v_*$ and $M$ because the post-shock temperature at the forward shock increases when the shocks are stronger. However, the H$\alpha$ emission is fainter by several orders of magnitude than our bow shock models for hot stars (see Figs 14 and 21). As a consequence, these bow shocks are not likely to be observed in H$\alpha$ because their H$\alpha$ surface brightnesses is below the detection sensitivity of the SHS (Parker et al. 2005).

Panel (b) of Fig. 17 plots the normalized cross-sections taken from the H$\alpha$ surface brightness and the dust surface mass density of the bow shock model RSG1020. The H$\alpha$ emission is maximum in the post-shock region at the forward shock, whereas the dust surface density peaks in the post-shock region at the reverse shock of the bow shock. All our models for bow shocks for RSG exhibit such comportment which suggests that H$\alpha$ and infrared emission do not originate from the same region of the bow shock. Because the RSG wind is denser than the ISM, most of the infrared emission probably originates from the shocked wind.

6 DISCUSSION

6.1 Comparison with previous works

6.1.1 Bow shocks around MS stars

We carried out tests with two numerical methods to integrate the parabolic term associated with heat conduction: the explicit method used in Comerón & Kaper (1998) and the Super-Time-Step method
The results are consistent between the two methods, except that the explicit scheme is less diffusive but also extremely time consuming. We adopt the Super-Time-Step algorithm given that the spatial resolution of our models is better than in Comerón & Kaper (1998).

We tested this method using the code PLUTO with respect to the models in Comerón & Kaper (1998). Our simulations support their study in that all the bow shocks are reproduced reasonably well. Our simulations that aim to reproduce the highly unstable simulation cases C (bow shock with strong wind) and E (bow shock in high density ambient medium) in Comerón & Kaper (1998) are slightly more affected by the development of overdensities at the apex of the structure which later govern the shape of the instabilities which distort the whole bow shocks. Our results vary depending on the chosen coordinate system and the interpolation scheme used at the symmetry axis. We conclude that instabilities growing at the apsis are artificially confined near $R = 0$ by the rotational symmetry imposed by the coordinate system.

Our models with $v_\star = 20 \text{ km s}^{-1}$ produce weak bow shocks. Such bow shocks correspond to the case A model in Comerón & Kaper (1998), which uses a similar wind velocity ($\sim 1000 \text{ km s}^{-1}$), and a mass-loss rate of $10^{-9} \text{M}_\odot \text{yr}^{-1}$ (i.e. 1.5 orders of magnitude larger, similar and one order of magnitude smaller than our 10, 20 and 40 $\text{M}_\odot$ stars, respectively), a less dense ISM ($0.1 \text{ cm}^{-3}$) and a much higher $v_\star$ ($\approx 100 \text{ km s}^{-1}$). Our models include cooling by forbidden collisionally excited lines and assume the same $T_{\text{ISM}} \approx 8000 \text{ K}$ as their case A. These models are similar because their weak forward shocks do not allow the gas to cool rapidly and they all have a region of shocked ISM thicker than the hot bubble along the direction of motion of the star, as signified by the absence of a sharp density peak in the region of shocked ISM in panel (a) of Fig. 12, compared to the lower panel of fig. 7 in Comerón & Kaper (1998).

Our models MS4040 and MS4070 have strong shocks and are similar to the case C model in Comerón & Kaper (1998). Their case C uses a higher $v_w \approx 3000 \text{ km s}^{-1}$, a slightly larger $M \sim 10^{-6} \text{M}_\odot \text{yr}^{-1}$, a less dense ISM ($0.1 \text{ cm}^{-3}$) and a higher $v_\star$ ($\approx 100 \text{ km s}^{-1}$). The combination of high $v_\star$ and high $v_w$ induces a strong compression factor at the forward shock where the gas cools rapidly and reduces the thickness of the shocked ISM into a thin, unstable shell. These models best fit analytical approximations of an infinitely thin bow shock (Comerón & Kaper 1998).

We conclude that for overlapping parameters, i.e. for similar $M$ and $v_\star$, our results agree well with existing models in terms of bow shock morphology and stability. We extend the parameter space for stars with weak winds, $M \approx 10^{-9.5}$ in our 10 $\text{M}_\odot$ model and use the typical particle density of the Galactic plane.
6.1.2 Bow shocks around RSG

We tested our numerical setup to reproduce the double bow shock around Betelgeuse (Mackey et al. 2012). Including heat conduction did not significantly change the results and we successfully reproduced the model using the same cooling curve as in Mackey et al. (2012). The simulations of RSG bow shocks of Mohamed et al. (2012) used a more precise time-dependent cooling network (Smith & Rosen 2003) and, because of their Lagrangian nature, these models are intrinsically better in terms of spatial resolution. To produce more detailed models which can predict emission line ratio is beyond the scope of this study but could be achieved using the native multi-ion non-equilibrium cooling module of the code PLUTO (Tesei, Mignone & Massaglia 2008).

Model RSG2020 shows a weak bow shock with a dense and cold shell expanding into the former hot and smooth bow shock. Rayleigh–Taylor instabilities develop at the discontinuity between the two colliding bow shocks as in the model of Betelgeuse’s multiple arched bow shock in Mackey et al. (2012).

Our simulations with $v_\star = 40$ km s$^{-1}$ show radiative forward shocks and unstable contact discontinuities. Model RSG1040 resembles the simulations of van Marle et al. (2011) and Decin et al. (2012) which have a similar $\dot{M} \approx 3 \times 10^{-6} M_\odot$ yr$^{-1}$ but a smaller $v_\star \approx 28$ km s$^{-1}$ and denser ISM (2 cm$^{-3}$). We do not use the two-fluid approach of van Marle et al. (2011) which allows the modelling of ISM dust grains and explains the differences in terms of stability of the contact discontinuity. Their simulation with type I grains is more unstable than our model RSG1040, probably because they use a denser ISM. Model RSG2040 has a thinner region of shocked ISM compared to the region of shocked wind which makes this model unstable. The instabilities of model RSG2040 are similar to the clumpy forward shock of models A–C in Mohamed et al. (2012) which have larger $\dot{M}$ and a denser medium.

Our simulations with $v_\star = 70$ km s$^{-1}$ show the largest compression. Model RSG2070 has a strongly turbulent shell with dramatic instabilities, consistent with the high $v_\star$ and high Mach number model in Blondin & Koerwer (1998). Our model RSG2070 illustrates the transverse acceleration instability where an isotropically expanding wind from the star meets the collinear ISM flow and pushes the developing eddies sideward. Model RSG2070 is different from the model D with cooling of Mohamed et al. (2012) which has a similar $v_\star \approx 72.5$ km s$^{-1}$ but a weaker wind $\dot{M} \approx 3.1 \times 10^{-6} M_\odot$ yr$^{-1}$. Because of its particular initial conditions, i.e. a hotter and diluted ISM with $n \approx 0.3$ cm$^{-3}$ and $T_{\text{ISM}} \approx 8000$ K, the gas does not cool efficiently at the forward shock and the post-shock regions of the bow shock remain isothermal, see the right-hand panel of fig. 10 of Mohamed et al. (2012).

With similar model parameters, our results agree well with the existing models and we conclude that heat conduction is not mandatory to model bow shocks from cool stars. Because we neglect the effects of dust dynamics on the bow shocks stability, our models differ slightly from existing models with $v_\star \approx 30$–40 km s$^{-1}$. However, this does not concern the overall shape of the bow shocks but
rather the (in)stability of their contact discontinuities. We extended the parameter space by introducing models with \( v_\star = 20 \text{ km s}^{-1} \).

### 6.2 On the observability of bow shocks from massive runaway stars

Fig. 23 plots the luminosities of our bow shock models for MS (top panels) and RSG (bottom panels) stars as a function of \( M_\star \) and \( v_\star \). With respect to their optically thin gas radiation, the brightest bow shocks produced by MS stars are generated by the more massive stars moving with a slow space velocity, e.g. the 40 M_\odot MS star moving with \( v_\star = 20 \text{ km s}^{-1} \), and the brightest bow shocks produced by RSG are generated by the more massive star of our sample, moving at high space velocity i.e. a 20 M_\odot RSG moving with \( v_\star = 70 \text{ km s}^{-1} \) (see panels a and d of Fig. 23). The same points arise from the luminosity of \( \text{H}_\alpha \) emission (see panels b and e of Fig. 23). The infrared luminosity indicates that the brightest bow shocks generated by a MS star are produced by high-mass, low-velocity stars (see panel c of Fig. 23). Concerning the bow shocks generated by RSG, their infrared luminosities suggest that the brightest are produced by high-mass stars moving at either low or high space velocities (see panel f of Fig. 23).

Because \( L_{\text{IR}} \) is larger than \( L_{\text{H}_\alpha} \) or \( L_{\text{gas}} \), the infrared waveband is the most appropriate to search for stellar-wind bow shocks around MS and RSG stars. According to our study, bow shocks produced by high-mass MS stars moving with low space velocities should be the easiest ones to observe in the infrared. The most numerous runaway stars have a low space velocity (Eldridge et al. 2011) and consequently bow shocks produced by high-mass RSG moving with low space velocity are the most numerous ones, and the probability to detect one of them is larger. Many stellar wind bow shocks surrounding hot stars ejected from stellar cluster are detected by means of their \( \leq 24 \mu\text{m} \) infrared signature (see Gvaramadze et al. 2010, 2011). Because our study focuses on the most probable bow shocks forming around stars exiled from their parent cluster, we expect them to be most prominent in that waveband.

Fig. 24 plots the bow shock luminosities for our MS models as a function of \( R(0)^3 \) (in pc\(^3\)) for the MS (large symbols) and RSG models (small symbols). The overplotted thin lines are least-squares fits of the luminosity of optically thin gas radiation (solid green line), the infrared luminosity of reprocessed starlight (dashed red line) and the luminosity of \( \text{H}_\alpha \) emission (dotted blue line).
7 CONCLUSION

We present a grid of hydrodynamical models of bow shocks around evolving massive stars. The runaway stars initial masses range from 10 to 40 M⊙ and their space velocities range from 20 to 70 km s⁻¹. Their evolution is followed from the MS to the RSG phase. Our simulations include thermal conduction and distinguish the treatment of the optically thin cooling and heating as a function of the evolutionary phase of the star.

Our results are consistent with Comerón & Kaper (1998) in that our bow shocks show a variety of shapes which usually do not fit a simple analytic approximation (Wilkin 1996). We stress the importance of heat conduction to model the bow shocks around MS stars and find that this is not an important process to explain the morphology of bow shocks around RSG. We underline its effects on their morphology and structure, especially concerning the transport of ISM material to the hot region of the bow shocks generated by hot stars. The heat transfer enlarges the bow shocks and considerably reduces the volume of shocked wind so that optical emission mainly originates from shocked ISM material. We extend the analysis of our results by calculating the luminosities of the bow shocks and detail how they depend on the star’s mass-loss and space velocity.

Our bow shock models of hot stars indicate that the main coolants governing their luminosities are the optical forbidden lines such as [O III] and [O III]. The luminosity of optical forbidden lines is stronger than the luminosity of Hα emission, which only represents less than a tenth of the luminosity by optically thin radiation. This agrees with the observations of Gull & Sofia (1979) who noticed that [O III] is a tenth of the luminosity by optically thin radiation. This agrees with governing their luminosities are the optical forbidden lines such as [O III] and [O III]. The luminosity of optical forbidden lines is stronger than the luminosity of Hα emission, which only represents less than a tenth of the luminosity by optically thin radiation. This agrees with the observations of Gull & Sofia (1979) who noticed that [O III] is a tenth of the luminosity by optically thin radiation. This agrees with the observations of Gull & Sofia (1979) who noticed that [O III] is a tenth of the luminosity by optically thin radiation. This agrees with the observations of Gull & Sofia (1979) who noticed that [O III] is a tenth of the luminosity by optically thin radiation.

The hereby presented grid of models will be enlarged in a wider study, and forthcoming work will investigate the effects of an ISM background magnetic field. We also plan to focus on the latest stellar evolutionary stage in order to model the final explosion happening at the end of the massive star life, because the supernova ejecta interact with the shaped circumstellar medium.

ACKNOWLEDGEMENTS

We thank the anonymous reviewer for his valuable comments and suggestions which greatly improved the quality of the paper. DM is grateful to Fernando Comerón for his help and comments. DM also acknowledges Richard Stanciliffe, Allard-Jan van Marle, Shazrene Mohamed and Hilding Neilson for very useful discussions. JM was partially supported by a fellowship from the Alexander von Humboldt Foundation. RGI thanks the Alexander von Humboldt Gesellschaft. This work was supported by the Deutsche Forschungsgemeinschaft priority programme 1573, ‘Physics of the Interstellar Medium’. Simulations were run thanks to a grant from John von Neumann Institute of computing time on the JUROPA supercomputer at Jülich Supercomputing Centre.

MNARAS 444, 2754–2775 (2014)
APPENDIX A: EMISSION MAPS AND PROJECTED DUST MASS

The simulations are post-processed in order to obtain projected Hα emission maps and ISM dust projected mass. The gas \( T \) is calculated according to equation (5). For every cell of the computational domain and for a given quantity \( \xi(T) \) representing either rate of emission (in erg s\(^{-1}\) cm\(^{-3}\)) or a density (in g cm\(^{-3}\)), we calculate its projection \( P_\xi \). The integral of \( \xi \) is performed inside the bow shock along a path perpendicular to the plane \((O, R, z)\), excluding the unperturbed ISM. Taking into account the projection factor, it is

\[
P_\xi(R, z) = 2 \int_{R'}^{R} \frac{\xi(R', z) R' dR'}{\sqrt{R'^2 - R^2}} \text{cm.}
\]  

For hot, photoionized medium, we use the Hα emissivity rate interpolated from the table 4.4 of Osterbrock & Boothkarev (1989), which is

\[
\xi(T) \approx 1.21 \times 10^{-22} T^{-0.9} n_e n_p \text{erg s}^{-1} \text{cm}^{-3} \text{sr}^{-1}.
\]  

where \( n_e \) and \( n_p \) are the number of electrons and protons per unit volume, respectively. For cool, CIE medium we employ a similar formalism, taking into account the fact that only the ions emit, i.e. the emission is proportional to \( n_i n_e \) with \( n_i \) the number of ions per unit volume. The emission rate is

\[
\xi(T) \approx 1.21 \times 10^{-22} T^{-0.9} n_i n_e \text{erg s}^{-1} \text{cm}^{-3} \text{sr}^{-1}.
\]  

The ISM projected dust mass is calculated integrating the number density. For a dust-to-gas ratio \( X_{d/g} \) and for the total gas number density \( n \), its expression is

\[
\xi(T) = n X_{d/g} \mu m_p \text{g cm}^{-3}.
\]  

We use a dust-to-gas ratio \( X_{d/g} = 1/200 \) by mass for the ISM (Neilsen et al. 2010; Neilsen, Cantillo & Langer 2011) and for the RSG winds (Lamers & Cassinelli 1999). The calculation of the dust density for bow shocks around hot stars also requires us to exclude from the integral in equation (A1) the region which are only made of wind material, i.e. which do not contain any dust.
APPENDIX B: ESTIMATION OF THE INFRARED EMISSION OF THE BOW SHOCKS

Learning from previous studies on the behaviour of dust in stellar bow shock (van Marle et al. 2011; Decin 2012; Decin et al. 2012), the infrared emission of a model is estimated as a part of the starlight absorbed by the dust grains and re-emitted at longer wavelengths, plus the gas collisional heating of the dust particles.

We assumed that the shocked ISM material into the outer layer of the bow shock is filled with spherical grains of radius $a = 4.5$ nm (van Marle et al. 2011) in a proportion of $X_d/g = 1/200$ by mass (Neilson et al. 2010, 2011). The interstellar grains are assumed to be made of silicates whose density is $\rho_g = 3.3 \text{ g cm}^{-3}$ (Draine & Lee 1984). The dust in the RSG wind is treated as in Mackey et al. (2012), but considering grains of radius $a = 5.0$ nm only. Such an approach is in accordance with interpretation of 24 $\mu$m infrared emission suggesting that small-size dust grains are not destroyed in ionized regions in the vicinity of young massive stars (Pavlyuchenkov, Kirsanova & Wiebe 2013). We assume that no dust crosses the material discontinuity, i.e. the shocked wind is dust-free in bow shocks around MS stars.

The flux from the starlight $L_*$ is intercepted at a distance $d$ from the star by the dust, which geometrical cross-section is $\sigma_d = \pi a^2 \text{ cm}^{-2}$. A part of the flux from the star is absorbed by the dust to be instantaneously re-radiated as

$$\Gamma_d = \frac{L_*}{4\pi d^2} n_d \sigma_d (1 - A) \text{ erg s}^{-1} \text{ cm}^{-3},$$

where $A = 1/2$ is the dust grain albedo (van Buren & McCray 1988). This assumes that the dust is not decoupled from the gas, which is realistic for ionized bow shocks, whereas it may not be true in bow shocks around cool stars (van Marle et al. 2011). This would influence both our estimation of $n_d$ and $\Gamma_d$.

Besides, we estimate the dust collisional heating rate $\Gamma_{d,dust}^{\text{coll}}(T)$. On the one hand, the collisional heating for a photoionized medium is computed following Ostriker & Silk (1973),

$$\Gamma_{d,dust}^{\text{coll,photo}}(T) = \frac{2^{5/2}}{\sqrt{\rho_p}} f Q n_d \sigma_d (k_B T)^{1/2} \text{ erg s}^{-1} \text{ cm}^{-3},$$

where $n_d$ is the dust number density, $m_p$ is the mass of the proton and $Q \approx 1$ is a correction due to the electrical properties of the grains. On the other hand, it is calculated for the CIE medium following Hollenbach & McKee (1979), with,

$$\Gamma_{d,dust}^{\text{coll,CIE}}(T) = 2k_B n_d \sigma_d f v_p \times (T - T_d) \text{ erg s}^{-1} \text{ cm}^{-3},$$

where $k_B$ is the Boltzman constant, $v_p = \sqrt{k_B T / m_p}$ is the proton thermal velocity, $f \approx 10$ is a parameter representing the effects of the species other than the protons and $T_d$ is the dust temperature,

$$T_d = 2.3 \left( \frac{f n_d}{a(\mu \text{m})} \left( \frac{T}{10^4 \text{ K}} \right) \right)^{1/5} \text{ K.}$$

In equation (B4), $a(\mu \text{m})$ is the dust radius expressed in $\mu \text{m}$. This method to calculate the infrared emission from a stellar wind bow shock is rather simple. It assumes that the starlight is re-emitted by the smallest possible grains and therefore constitute an upper limit of the corresponding luminosity. For all models, it was found that radiative heating is dominant over collisional heating for all regions within the bow shock.
