ABSTRACT

X-ray observations of quiescent X-ray binaries have the potential to provide insight into the structure and the composition of neutron stars. EXO 0748–676 had been actively accreting for over 24 yr before its outburst ceased in late 2008. Subsequent X-ray monitoring revealed a gradual decay of the quiescent thermal emission that can be attributed to cooling of the accretion-heated neutron star crust. In this work, we report on new *Chandra* and *Swift* observations that extend the quiescent monitoring to $\simeq 5$ yr post-outburst. We find that the neutron star temperature remained at $\simeq 117$ eV between 2009 and 2011, but had decreased to $\simeq 110$ eV in 2013. This suggests that the crust has not fully cooled yet, which is supported by the lower temperature ($\simeq 95$ eV) measured $\simeq 4$ yr prior to the accretion phase in 1980. Comparing the data to thermal evolution simulations reveals that the apparent lack of cooling between 2009 and 2011 could possibly be a signature of convection driven by phase separation of light and heavy nuclei in the outer layers of the neutron star.

Key words: accretion, accretion disks – binaries: eclipsing – stars: individual (EXO 0748–676) – stars: neutron – X-rays: binaries

1. INTRODUCTION

Transient neutron star low-mass X-ray binaries (LMXBs) are excellent laboratories for increasing our understanding of the structure and the composition of neutron stars, and how matter behaves under extreme physical conditions. In these binary star systems, a neutron star is accompanied by a late-type star that overflows its Roche lobe and transfers matter to an accretion disk. This matter is rapidly accreted onto the neutron star during outburst episodes, whereas little or no matter reaches the compact primary during quiescent intervals.

These accretion cycles have a profound effect on the interior properties of neutron stars. They cool during quiescence as they lose thermal energy via photons emitted from their surface and neutrinos escaping from their crust and core (e.g., Yakovlev et al. 2003; Page et al. 2006; Steiner & Reddy 2009; Schatz et al. 2014). However, neutron stars can re-gain thermal energy during accretion outbursts.

The accretion of matter compresses the crust of a neutron star, which causes successive electron captures, neutron emissions and pycno-nuclear fusion reactions. Together, these processes deposit an energy of $\simeq 2$ MeV per accreted nucleon in the crustal layers (e.g., Haensel & Zdunik 1990a, 1990b; Gupta et al. 2007; Steiner 2012). This energy is thermally conducted both toward the stellar core and surface, and can effectively maintain the interior temperature of the neutron star at $\simeq 10^7$ – 10^8 K. This temperature is set by the energy injected during its historic accretion activity and the efficiency of the neutrino cooling

processes (e.g., Brown et al. 1998; Colpi et al. 2001; Yakovlev et al. 2003; Wijnands et al. 2013).

During quiescent episodes, thermal X-rays from the surface of the neutron star may be detected. This allows a measurement of its temperature, which can encode valuable information about its interior properties. Of particular interest are observations obtained shortly after the cessation of an outburst; heating due to accretion may lift the temperature of the crust well above that of the stellar core and the subsequent cooling may be observable once back in quiescence (Wijnands et al. 2001; Ushomirsky & Rutledge 2001; Rutledge et al. 2002).

Indeed, dedicated X-ray monitoring of six LMXBs (KS 1731–260, MXB 1659–29, XTE J1701–462, EXO 0748–676, IGR J17480–2446, and MAXI J0556–332), revealed that the temperature of the neutron star decreased for years following the cessation of accretion, consistent with the heating/cooling paradigm (e.g., Wijnands et al. 2002, 2004; Cackett et al. 2006, 2008, 2010a; Degenaar et al. 2009, 2011a, 2011b, 2013a; Díaz Trigo et al. 2011; Fridriksson et al. 2010, 2011; J. Homan et al., in preparation). Comparison with thermal evolution simulations has yielded valuable insight into the thermal and transport properties of neutron star crusts (Shternin et al. 2007; Brown & Cumming 2009; Degenaar et al. 2011a; Page & Reddy 2013; Turlione et al. 2013).

Despite these successes, interpretation of the quiescent thermal emission and crustal cooling is complicated by the question whether accretion onto the neutron star fully comes to a halt. Searching for (strong) non-thermal emission in the quiescent X-ray spectrum, irregular quiescent X-ray variability, or optical/UV signatures of the quiescent accretion stream can

Notes. The listed exposure times and count rates are not corrected for eclipses. The count rates refer to the 0.3–10 keV energy band. Errors represent 90% confidence levels.

shed light on whether residual accretion occurs (see, e.g., Cackett et al. 2010b, 2011, 2013b; Degenaar & Wijnands 2012; Bernardini et al. 2013, for recent studies).

1.1. EXO 0748–676

The neutron star LMXB EXO 0748–676 was discovered almost three decades ago (Parmar et al. 1985). The detection of X-ray eclipses indicates that the binary is viewed at high inclination ($i \simeq 75^\circ$ – 83°), and led to a measurement of the orbital period ($\simeq 3.82$ hr; Parmar et al. 1986; Wolff et al. 2009). The source displays thermonuclear X-ray bursts, which allows for a distance determination ($\simeq 7$ kpc; e.g., Galloway et al. 2008).

EXO 0748–676 was first detected in outburst in 1984 with *EXOSAT* (Reynolds et al. 1999), and was serendipitously detected in quiescence with *Einstein* in 1980 (Parmar et al. 1986; Garcia & Callanan 1999). The source remained in outburst for $\simeq 24$ yr and during this time the flux was moderately stable with occasional excursions to higher and lower fluxes. However, its activity suddenly ceased in 2008 September (Wolff et al. 2008a, 2008b; Hynes & Jones 2008; Torres et al. 2008). Subsequent monitoring with *Swift*, *Chandra* and *XMM-Newton* revealed a relatively hot neutron star that gradually cooled over time (Degenaar et al. 2009, 2011b; Díaz Trigo et al. 2011).

In this work we report on new X-ray observations of EXO 0748–676 to further monitor how the accretion-heated crust cools, and to search for signs of continued low-level accretion. We also re-analyze the *Einstein* data obtained in 1980 to measure the pre-outburst temperature of the neutron star. We then compare the entire data set to crust cooling simulations.

2. OBSERVATIONS AND DATA ANALYSIS

Table 1 gives an overview of all new *Chandra* and *Swift* data of EXO 0748–676. A list of earlier X-ray observations obtained during the quiescent phase can be found in Degenaar et al. (2009), Degenaar et al. (2011b), and Díaz Trigo et al. (2011). To benefit from the latest calibration updates and to ensure a homogeneous analysis, these quiescent X-ray observations were re-reduced and re-analyzed in this work.

2.1. New *Chandra* Observations

We obtained three new *Chandra* observations of EXO 0748–676 between 2010 October and 2013 August (Table 1). The setup was similar to previous quiescent observations of the source, using the S3 chip of the Advanced CCD Imaging Spectrometer (ACIS; Garmire et al. 2003). The ACIS-S3 CCD was operated in a 1/8 sub-array during the 2010 observation and in a 1/4 sub-array during the 2011/2013 observations. We reduced the data using the CIAO package (ver. 4.5). All observations were free from background flaring.

We extracted source events using a circular region of $3''$ radius centered on EXO 0748–676, and a $10''$ – $25''$ annulus was used to estimate the background (excluding a circular region with a $2''$ radius centered on a faint point source). Count rates and light curves were extracted using the task DMEXTRACT. Source and background spectra, as well as the corresponding response files, were created using the meta task SPEXTRACT. We used GRPPHA to group the spectra into bins of at least 20 photons. About 3800–6400 net source events were collected for each *Chandra* observation.

The light curves obtained from the individual observations clearly show the presence of eclipses at times consistent with the ephemeris of Wolff et al. (2009). During the eclipses, the X-ray emission from the neutron star is temporarily blocked by the companion. To calculate the time-averaged X-ray fluxes excluding the eclipsed epochs, we therefore reduced the exposure times of all *Chandra* observations by 500 s per eclipse (which is the observed duration of the eclipses in quiescence; Bassa et al. 2009).

2.2. New *Swift* Observations

EXO 0748–676 has been observed with the X-Ray Telescope (XRT; Burrows et al. 2005) on board *Swift* many times since it transitioned to quiescence (see Wolff et al. 2008a, 2008b; Degenaar et al. 2009, 2011b). Here we report on 11 new observations that were carried out between 2010 May and 2013 March (see Table 1). All XRT data were obtained in the photon-counting mode.

The *Swift* observations were reduced using the HEASOFT suite (ver. 6.13). We first processed the raw XRT data using the XRTPipeline. Employing XSELECT, we then extracted source events using a circular region with a radius of $35''$, which optimized the signal-to-noise ratio for the observed count rates (cf. Evans et al. 2007). A surrounding annular region of radius $100''$ – $200''$ was used as a background reference. We obtained $\simeq 50$ – 350 net source counts per observation.

The *Chandra* and *XMM-Newton* observations provide superior spectral quality compared to the short *Swift*/XRT pointings. However, the *Swift* data offer unique dense sampling that allows us to closely track intensity variations occurring on a timescale of days–weeks. For the *Swift* data we therefore focused our attention on the long-term quiescent light curve. The count rates extracted for each observation were corrected for losses due to bad pixels and bad columns. Due to the relatively low count rates, it was not possible to identify eclipses in the data. We therefore checked the good time intervals against the ephemeris of Wolff et al. (2009); if (part of) eclipses were expected, we reduced the exposure times accordingly.

2.3. Archival *XMM-Newton* Observations

Following its return to quiescence, EXO 0748–676 was observed with the European Photon Imaging Camera (EPIC;

Notes. Quoted uncertainties represent 90% confidence intervals. F_{X} represents the total unabsorbed model flux and $F_{\text{X,th}}$ gives the thermal flux (0.5–10 keV). The ratio of these two fluxes, f_{th} , represents the fractional contribution of the thermal emission to the total model flux. $F_{\text{bol,th}}$ represents the unabsorbed thermal flux in the 0.01–100 keV energy band. The 0.5–10 keV total model luminosity (L_{X}) and the thermal bolometric luminosity ($L_{\text{bol,th}}$) are for a distance of $D = 7.1$ kpc.

Strüder et al. 2001; Turner et al. 2001) on board *XMM-Newton* on four occasions (Bassa et al. 2009; Díaz Trigo et al. 2011). We reduced and analyzed these data using the *SAS* package (ver. 13.0). After reprocessing with *EMPROC* and *EPPROC*, and removing background flaring events, we extracted spectra and light curves using the task *EVSELECT*. A circular region with a radius of $35''$ was used for the source and a $70''$ radius circular region placed on an empty part of the CCD served as the background.

Response files were generated using *ARFGEN* and *RMFGEN*. The spectra and response files of the three detectors (MOS1, MOS2, and PN) were combined with the tool *EPICSPECCOMBINE*.¹² Using *GRPPHA* we grouped the spectral data to contain at least 20 photons per bin. The number of net source counts collected for each *XMM-Newton* observation was $\simeq 24,000$ – $45,000$ (all three EPIC instruments summed). Similar to our treatment of the *Chandra* data, the exposure times of the observations were reduced with 500 s per eclipse.

2.4. Pre-outburst *Einstein* Observation

EXO 0748–676 was serendipitously detected with the Imaging Proportional Counter (IPC) on board the *Einstein* observatory on 1980 May 22 (ObsID 7708; Parmar et al. 1986; Garcia & Callanan 1999). The source intensity during the $\simeq 5.8$ ks exposure was $\simeq (1.7 \pm 0.2) \times 10^{-2} \text{ counts s}^{-1}$, whereas the local background is estimated at $\simeq (0.6 \pm 0.1) \times 10^{-2} \text{ counts s}^{-1}$. We created spectra and response files using *XSELECT*. Source events were collected from a region of 20 pixels ($2''/7$), and background events using a source-free region of twice that size. Extrapolating the ephemeris of Wolff et al. (2009) back to the time of the *Einstein* observation suggests that the source may have been eclipsed for $\simeq 230$ s. We therefore reduced the exposure time by this amount.

There is little reported information in the literature about cross-calibration between the *Einstein*/IPC and the current generation of X-ray instruments (e.g., the Crab was too bright for the IPC; Kirsch et al. 2005). A study of nova-like variables

yielded strong consistency with *ROSAT*/PSPC results, lending credence to the low-energy response of the IPC (Verbunt et al. 1997). Systematic uncertainties are estimated to be at the 10%–15% level (e.g., Fabricant et al. 1984; David et al. 1990). To account for (cross-)calibration uncertainties, we included a conservative 20% systematic error for the *Einstein* data in our spectral fits.

2.5. Spectral Fitting Procedures

The *Chandra*, *XMM-Newton* and *Einstein* spectra (each with their own response and background files) were fitted simultaneously in the 0.3–10 keV energy range using *XSPEC* (ver. 12.8; Arnaud 1996). The *Einstein* data and the last three *XMM-Newton* observations were all dominated by background noise above an energy of $\simeq 3$ keV (see also Díaz Trigo et al. 2011). For these observations we therefore excluded the data above 3 keV.

Expanding on previous work (Degenaar et al. 2009, 2011b; Díaz Trigo et al. 2011), we concentrated on fitting the data to a combination of a neutron star atmosphere model (NSATMOS; Heinke et al. 2006) and a power law (PEGPWRL; to model any possible non-thermal emission). To account for the neutral hydrogen absorption along the line of sight, N_{H} , we included the TBABS model adopting the VERN cross-sections and WILM abundances (Verner et al. 1996; Wilms et al. 2000).

Since EXO 0748–676 is viewed at a relatively high inclination and hence the absorption along the line of sight could be variable (see, e.g., Cackett et al. 2013a), we allowed N_{H} to change between the different observations. Only for the *Einstein* spectrum we could not obtain good constraints on N_{H} . For this data set we therefore fixed N_{H} to the average value obtained for the *Chandra* and *XMM-Newton* spectra (Table 2).

For the NSATMOS model we fixed the normalization at unity, i.e., we assumed that the emitting area was the same during all observations and corresponded to the entire neutron star surface. When fixing the neutron star mass and radius to $M_{\text{NS}} = 1.4 M_{\odot}$ and $R_{\text{NS}} = 10$ km, no acceptable fit could be obtained (see also Degenaar et al. 2009, 2011b; Díaz Trigo et al. 2011). Both parameters were therefore left free to find the best-fit values (assuming that M_{NS} and R_{NS} did not change over time, they

¹² For all four *XMM-Newton* observations we found that the fits results for the combined PN/MOS spectra were consistent with fits to the separate PN and MOS spectra.

were tied between the different data sets). The source distance was not well constrained when left to vary freely and drove the neutron star mass and radius to unrealistic values. We therefore fixed the distance to $D = 7.1$ kpc in all spectral fits (Galloway et al. 2008). The neutron star temperature was allowed to vary freely.

For the non-thermal emission component it was not possible to constrain the power-law index for each observation individually. We therefore chose to fix this parameter for the entire data set to the value obtained from the first *XMM-Newton* observation, which provided the best constraints ($\Gamma = 1.7$; Degenaar et al. 2011b). The power-law normalization was free to vary.

From the fit results we calculated the effective neutron star temperature as seen by an observer at infinity, $kT_{\text{eff}}^{\infty} = kT_{\text{eff}}/(1+z)$. Here, $(1+z) = (1 - R_s/R_{\text{NS}})^{-1/2}$ is the gravitational redshift factor, with $R_s = 2GM_{\text{NS}}/c^2$ being the Schwarzschild radius, G the gravitational constant and c the speed of light. Using *CFLUX* in *XSPEC*, we determined the unabsorbed 0.5–10 keV flux and the thermal bolometric flux. The latter was estimated by extrapolating the *NSATMOS* model component to the 0.01–100 keV energy range. All fluxes were converted to luminosities by assuming $D = 7.1$ kpc.

3. RESULTS

3.1. X-Ray Spectral Evolution

Simultaneously fitting the *Chandra*, *XMM-Newton*, and *Einstein* spectra to a combined neutron star atmosphere and power-law model as described in Section 2.5 resulted in a reduced chi-squared value of $\chi_v^2 = 1.00$ for 1950 degrees of freedom (dof) with a p value of $p_{\chi} = 0.46$. The best fit yielded a neutron star mass of $M_{\text{NS}} = 1.64 \pm 0.38 M_{\odot}$ and a radius of $R_{\text{NS}} = 13.2^{+0.6}_{-2.0}$ km. The uncertainty in M_{NS} dominates the errors in all other parameters (see also the discussion in Díaz Trigo et al. 2011). For the error calculation we therefore fixed $M_{\text{NS}} = 1.64 M_{\odot}$ at the best-fit value (whereas R_{NS} was still free). The results are summarized in Table 2.

We find that the values of N_{H} obtained for the *XMM-Newton* data are systematically lower than for the *Chandra* observations. This likely arises due to cross-calibration uncertainties (Kirsch et al. 2005; Degenaar et al. 2011b; Tsujimoto et al. 2011).¹³ Nevertheless, the temperature evolution shows the same trend across the two data sets, indicating that the difference in N_{H} does not affect the relative temperature changes (see also Díaz Trigo et al. 2011). There is little variation in N_{H} among the *Chandra* observations, and the same is true for the *XMM-Newton* data set. It therefore appears there are no large changes in the absorption along the line of sight between 2008 and 2013, despite the binary being viewed at high inclination.

The first *Chandra* and first *XMM-Newton* observation (obtained within two months after the outburst) required the presence of a hard spectral component, although its contribution to the total 0.5–10 keV flux was small ($\lesssim 15\%$; Degenaar et al. 2011b; Díaz Trigo et al. 2011). This non-thermal component is not statistically required in subsequent observations, although it may still account for up to $\simeq 10\%$ of the 0.5–10 keV flux (Table 2). The quiescent spectra of EXO 0748–676 are thus strongly

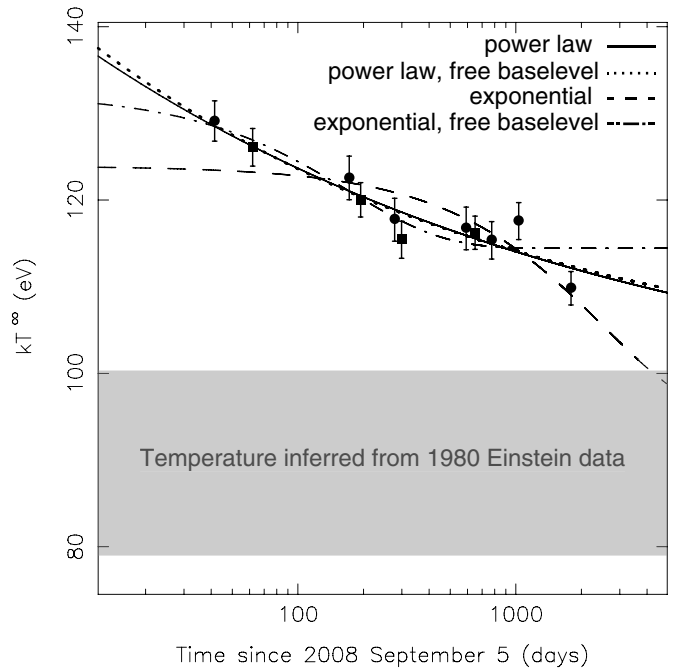

Figure 1. Evolution of the neutron star temperature from *Chandra* (filled circles) and *XMM-Newton* (squares) data. Shown are power-law (solid) and exponential (dashed) decay fits with a base level set to the pre-outburst temperature measured in 1980 (gray shaded area). The dotted (power law) and dashed-dotted (exponential) lines are decay fits with the quiescent base level left as a free parameter. Error bars indicate 90% confidence levels.

dominated by soft, thermal emission throughout the quiescent phase (see also Section 4.3).

The neutron star temperature gradually decreased by $\simeq 11$ eV within the first year after the outburst (2008 October till 2009 June), but showed little change in the subsequent two years. Indeed, requiring the temperatures of the 6 observations obtained between 2009 June and 2011 July to be the same results in a good fit ($\chi_v^2 = 1.01$ for 1955 dof, $p_{\chi} = 0.39$), with an average temperature of $kT_{\text{eff}}^{\infty} = 116.7 \pm 1.9$ eV. It therefore appeared that the neutron star crust had fully cooled well within two years of entering quiescence (Degenaar et al. 2011b; Díaz Trigo et al. 2011). However, our *Chandra* observation obtained in 2013 August ($\simeq 4.9$ yr after the outburst) shows a decrease in temperature by $\simeq 7$ eV compared to 2009–2011 (Table 2). This is illustrated by Figure 1, which shows the evolution of the temperature over time. Forcing the 2013 temperature to be the same as during the previous six observations results in a poor fit ($\chi_v^2 = 1.07$ for 1956 dof, $p_{\chi} = 0.02$).

Since we found little variation in the absorption along the line of sight, the drop in temperature observed in 2013 appears to be genuine, and hence indicates continued or accelerated cooling of the neutron star (see Section 3.2). This is supported by the fact that the temperature inferred from the pre-outburst *Einstein* observation ($\simeq 95$ eV) is lower than in our latest *Chandra* observation (see Table 2 and Figure 1). We note that different values of N_{H} , D , M_{NS} , and R_{NS} may shift the absolute temperatures by a few ($\lesssim 10$) eV. However, the observed relative temperature change, i.e., the crust cooling curve, is not affected by these systematic uncertainties.

3.2. Crust Cooling Curve Fits

To characterize the temperature evolution of EXO 0748–676 and compare it with that of other sources, we fitted the crust

¹³ We note that in Degenaar et al. (2011b), it was found that the first *XMM-Newton* observation had an elevated temperature compared to adjacent *Chandra* and *Swift* observations. In those spectral fits, N_{H} was fixed between the different data sets. Here we leave N_{H} free, which does not yield an elevated temperature for the first *XMM-Newton* observation (see Table 2 and Figure 1).

Table 3
Decay Fits to the Crust Cooling Curve

Fit Parameter (unit)	Value
Exponential decay, base level fixed	
Normalization, a (eV)	29.3 ± 1.1
Decay time, τ (days)	2533.8 ± 458.1
Constant offset, b (eV)	94.6 fixed
χ^2_v (dof)	2.2 (9)
P_χ	0.02
Exponential decay, base level free	
Normalization, a (eV)	17.9 ± 3.2
Decay time, τ (days)	172.1 ± 51.7
Constant offset, b (eV)	114.4 ± 1.2
χ^2_v (dof)	1.1 (10)
P_χ	0.40
Power-law decay, base level fixed	
Normalization, a (eV)	64.9 ± 8.4
Decay index, α	0.18 ± 0.02
Constant offset, b (eV)	94.6 fixed
χ^2_v (dof)	0.8 (9)
P_χ	0.58
Power-law decay, base level free	
Normalization, a (eV)	65.4 ± 10.2
Decay index, α	0.21 ± 0.03
Constant offset, b (eV)	99.1 ± 2.3
χ^2_v (dof)	0.8 (10)
P_χ	0.68
Power-law decay, no constant offset	
Normalization, a (eV)	146.5 ± 4.2
Decay index, α	0.04 ± 0.01
Constant offset, b (eV)	0 fixed
χ^2_v (dof)	0.9 (9)
P_χ	0.54

Notes. The data was fit to an exponential decay of the form $y(t) = ae^{-(t-t_0)/\tau} + b$, and a power-law decay shaped as $y(t) = a(t-t_0)^{-\alpha} + b$. The fixed constant offset of $b = 94.6$ eV corresponds to the temperature inferred from the pre-outburst *Einstein* observation. The power-law fit without constant offset is included to allow for a comparison with the literature. In all fits, the start of the cooling curve, t_0 , was set to 2008 September 5 (MJD 54714; Degenaar et al. 2009).

cooling curve to an exponential decay of the form $y(t) = ae^{-(t-t_0)/\tau} + b$. Here, a is a normalization, τ the e -folding time, and b represents the quiescent base level. The reference time t_0 is set to the presumed end of the outburst, 2008 September 5 (MJD 54714; Degenaar et al. 2009). Fixing $b = 94.6$ eV to the 1980 level does not provide an acceptable fit (yielding $\chi^2_v = 2.2$ for 9 dof, $p_\chi = 0.02$). The fit improves when the base level is allowed to vary ($\chi^2_v = 1.1$ for 10 dof, $p_\chi = 0.40$), but the obtained value of $b = 114.4 \pm 1.2$ eV is higher than observed with *Chandra* in 2013 ($b = 109.9 \pm 2.0$ eV). An exponential decay therefore may not be a good representation of the crust cooling curve of EXO 0748–676 (dashed and dashed-dotted lines in Figure 1).

We also fitted the data to a power-law function of the form $y(t) = a(t-t_0)^{-\alpha} + b$, which is the theoretically expected shape for a cooling crust (e.g., Brown & Cumming 2009). Fixing $b = 94.6$ eV to the *Einstein* level yields a good fit with a decay index of $\alpha = 0.18 \pm 0.02$ ($\chi^2_v = 0.8$ for 9 dof, $p_\chi = 0.58$). With the constant offset allowed to vary we found $b = 99.1 \pm 2.3$ eV

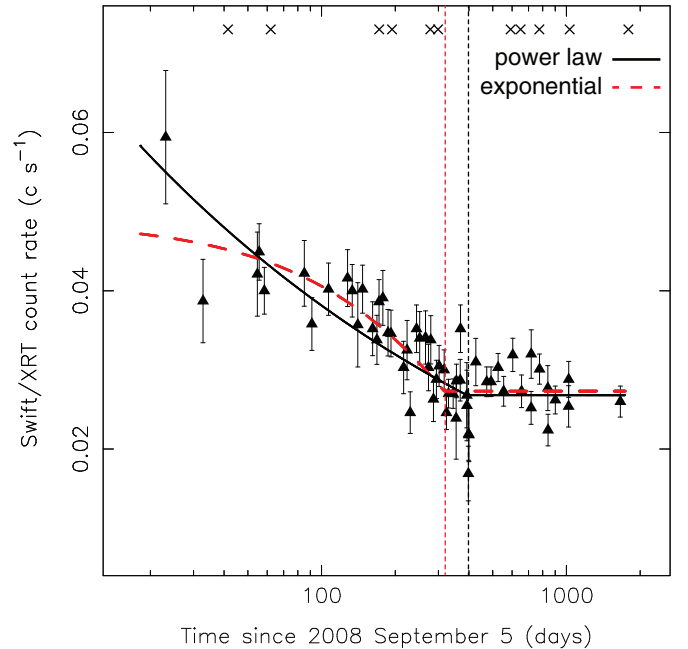

Figure 2. *Swift*/XRT count rate light curve covering the epoch of 2008–2013 after the source transitioned to quiescence (binned per observation). The black solid and red dashed lines represent fits to an exponential and a power-law decay, respectively (leveling off to a constant). The black and red dotted lines indicate the times of a transition to a constant level for these fits. The markers on top indicate the times of *Chandra* and *XMM-Newton* observations. Error bars represent 90% confidence intervals.

(A color version of this figure is available in the online journal.)

and $\alpha = 0.21 \pm 0.03$ ($\chi^2_v = 0.8$ for 10 dof, $p_\chi = 0.68$). The base level we obtain is consistent within the errors with the *Einstein* measured temperature. The power-law decay fits are indicated by the solid and dotted lines in Figure 1.

The results of the exponential and power-law decay fits are summarized in Table 3. In the literature the crust cooling curves are often fit to a power-law decay without a constant offset. Since the inclusion of a base level changes the resulting slope significantly, we also reference a fit without a constant level to allow for a direct comparison with other sources.

3.3. *Swift* Quiescent X-Ray Light Curve

The 2008–2013 *Swift*/XRT count rate light curve of EXO 0748–676 is shown in Figure 2. The source intensity changed gradually from $\simeq 6 \times 10^{-2}$ to $\simeq 2.5 \times 10^{-2}$ counts s^{-1} within the first year after the outburst, but showed little variation thereafter. Simple decay fits with an exponential ($\chi^2_v = 1.5$ for 56 dof) or a power-law function ($\chi^2_v = 1.7$ for 56 dof) leveling off to a constant suggests that the quiescent light curve flattened $\simeq 1$ yr post-outburst (Figure 2). This may indicate an episode of relatively constant intensity, as was also hinted by our analysis of the *Chandra*/*XMM-Newton* spectral data (Section 3.1). The *Swift* spectral data is not of sufficient quality to test whether the last data point (obtained in 2013 March) supports the lower temperature seen during the 2013 August *Chandra* observation.

There is also more stochastic variability among the data points, although the 90% error bars largely overlap. Since we corrected the count rates for dead zones on the CCD and the possible occurrence of eclipses (Section 2.2), we suspect that the variations are due to photon statistics (this is perhaps supported by the fact that the largest outliers in the light curve concern short observations, i.e., which collected a small number of photons). It

Table 4
Thermal Evolution Models

Parameter (unit)	No Convection	Convection
Q_{imp}	40	40
Q_{extra} (MeV nucleon $^{-1}$)	1.8	1.8
X_b	0.30	0.37
T_{core} (K)	1.50×10^8	1.35×10^8

Notes. Q_{imp} represents the impurity parameter, Q_{extra} the additional heat energy (placed at a column depth of $y = 1 \times 10^{12}$ g cm $^{-2}$), X_b the mass fraction of oxygen at the base of the liquid ocean, and T_{core} the core temperature. We assumed an outburst duration of $t_{\text{ob}} = 24$ yr, and mass-accretion rate of $\dot{M}_{\text{ob}} = 3 \times 10^{16}$ g s $^{-1}$. The equation of state used in these simulations results in $M_{\text{NS}} = 1.62 M_{\odot}$ and $R_{\text{NS}} = 11.2$ km (for details, see Medin & Cumming 2014).

is clear that there are no strong intensity flares as are sometimes seen in quiescent neutron star LMXBs (see Section 4.3).

3.4. Thermal Evolution Simulations

We briefly explored thermal evolution simulations to gauge the properties of the neutron star in EXO 0748–676. Using the physical model described in Brown & Cumming (2009) and Medin & Cumming (2014), we calculated source-specific cooling curves assuming an outburst duration of $t_{\text{ob}} = 24$ yr and an outburst mass-accretion rate of $\dot{M}_{\text{ob}} = 3 \times 10^{16}$ g s $^{-1}$ (e.g., Degenaar et al. 2011b). The model parameters which are then adjusted to match the data are the core temperature T_{core} and the impurity parameter Q_{imp} . The latter parameterizes how organized the structure of the ion lattice is, and hence determines the thermal conductivity (e.g., Itoh & Kohyama 1993; Brown & Cumming 2009).

In recent years, evidence has accumulated that there is more heat generated in the crusts of neutron stars than is currently accounted for by nuclear heating models (e.g., Brown & Cumming 2009; Degenaar et al. 2011a, 2013b; Schatz et al. 2014). We therefore allowed for the inclusion of an additional heat source Q_{extra} placed at a column depth of $y = 1 \times 10^{12}$ g cm $^{-2}$. Table 4 gives an overview of the model calculations.

We find that reproducing the observed high temperatures of EXO 0748–676 requires a crust impurity parameter of $Q_{\text{imp}} = 40$, and an additional heat source of $Q_{\text{extra}} = 1.8$ MeV nucleon $^{-1}$. This model produces the data reasonably well (dashed curve in Figure 3). It suggests that the source has so far moved along a continuous cooling track and will reach its pre-outburst quiescent level many years from now.

Interestingly, the occurrence of a possible plateau of slow cooling in EXO 0748–676 starting $\simeq 1$ yr post-outburst (Sections 3.1 and 3.3) resembles recent calculations of Medin & Cumming (2014). These authors showed how cooling curves are affected by a convective heat flux that arises when light and heavy nuclei in the crust separate out in liquid and solid phases (Horowitz et al. 2007; Medin & Cumming 2011). Therefore, we also performed model calculations with compositionally driven convection taken into account. This introduces one extra fit parameter, X_b , which is the mass fraction of oxygen at the base of the liquid ocean (for details, see Medin & Cumming 2014).

We find that the inclusion of convection leads to a plateau of slow cooling between $\simeq 150$ –750 days post-outburst, broadly consistent with the data (solid curve in Figure 3). This arises because the compositionally driven convection transports heat inward, temporarily slowing the cooling in the crustal layers

Figure 3. Crust cooling curve of EXO 0748–676 constructed from *Chandra* (filled circles) and *XMM-Newton* (squares) data. The solid and dashed curves represent model calculations with and without convection taken into account, respectively (see Section 3.4 for details). The late-time wiggles in the convection curve (near $\simeq 4000$ and 9000 days post-outburst) are numerical artifacts. The gray shaded area indicates the pre-outburst temperature. Error bars represent 90% confidence intervals.

where the phase separation occurs. We note that the model including convection is not statistically preferred over the non-convective case.

4. DISCUSSION

4.1. Crustal Cooling in EXO 0748–676

Our new *Chandra* and *Swift* observations of EXO 0748–676 extend the quiescent monitoring to $\simeq 4.9$ yr after the cessation of its very long ($\simeq 24$ yr) active period. We find that the neutron star temperature gradually decreased during this time, consistent with expectations for cooling of the accretion-heated neutron star crust. In the first year of quiescence, between 2008 and 2009, the temperature decreased from $kT_{\text{eff}}^{\infty} \simeq 129$ to 118 eV. It then hovered around 117 eV for at least $\simeq 2$ yr until 2011, but our most recent observation obtained in 2013 indicates a further decrease in temperature to $kT_{\text{eff}}^{\infty} \simeq 110$ eV.

Despite the high inclination of the binary, there are no indications that the lower temperature in 2013 is due to a changing absorption column density, such as possibly seen in MXB 1659–29 (Cackett et al. 2013a). Whereas the apparent lack of temperature evolution after 2009 led to the suggestion that the neutron star crust restored equilibrium with the core (Degenaar et al. 2011b; Díaz Trigo et al. 2011), the new data presented in this work suggests that cooling is still ongoing and that a further decrease in temperature may be expected.¹⁴ This

¹⁴ Degenaar et al. (2011b) noted that the *Einstein* flux reported by Garcia & Callanan (1999) was consistent within the errors with that inferred from the 2010 *Chandra* data. However, Garcia & Callanan (1999) used a different physical model to fit the spectrum, which may introduce biases. Fitting the data in tandem with the post-outburst *Chandra* and *XMM-Newton* observations suggests that the pre-outburst temperature was lower than currently seen, provided the caveats mentioned in Section 2.4.

is supported by the lower temperature measured $\simeq 4$ yr prior to the outburst in 1980; $kT_{\text{eff}}^{\infty} \simeq 95$ eV.

4.2. A Signature of Convection?

The possible ‘‘plateau’’ of stalled cooling starting $\simeq 1$ yr post-outburst is reminiscent of the crust cooling curve of XTE J1701–462. That source also appeared to level off within $\simeq 2$ yr of entering quiescence (Fridriksson et al. 2011), but Page & Reddy (2013) predicted that after a temporary plateau an accelerated temperature decay would occur, which seems to be borne out by more recent observations (J. K. Fridriksson et al., in preparation). XTE J1701–462 experienced a relatively short ($\simeq 1.6$ yr) but very bright accretion phase (an average flux near the Eddington limit). As a result of this vigorous heating, the temperature in the crust likely did not reach a steady state but rather had a double-peaked profile, which would naturally give rise a plateau. This is in sharp contrast to EXO 0748–676, which was active for 24 yr at relatively low X-ray flux ($\simeq 5\%$ of Eddington), implying that the crust had ample time to reach a steady state profile (see Brown & Cumming 2009).

Another mechanism that may cause a plateau in the cooling curve is a convective heat flux driven by chemical separation of light and heavy nuclei in the outer layers of the neutron star (Horowitz et al. 2007; Medin & Cumming 2011, 2014). Inclusion of the inward heat transport by compositionally driven convection in the model calculations for EXO 0748–676 leads to an episode of slow cooling that is broadly consistent with the observations. The crust cooling curve of EXO 0748–676 may thus bear an imprint of this process, although the data can also be satisfactory modeled without convection. Perhaps another possibility is that a crustal shell of rapid neutrino cooling as recently identified by Schatz et al. (2014) is connected to the period of stalled cooling. This process is highly temperature-sensitive and may be related to the fact that a plateau appears to be seen only in the two hottest crust-cooling neutron stars EXO 0748–676 and XTE J1701–462. However, this could also be an observational bias, since these two sources were more intensely monitored than the others (see Degenaar et al. 2011b, for a comparison). Further theoretical investigation is required to grasp the implications of this newly identified cooling process on neutron star crust cooling curves.

It is of note that the model calculations of EXO 0748–676 require rather high values for the impurity parameter ($Q_{\text{imp}} = 40$), and the additional heat ($Q_{\text{extra}} = 1.8$ MeV nucleon $^{-1}$), to keep the crust hot as long as observed. In contrast, the crust cooling curves of KS 1731–260, MXB 1659–29, XTE J1701–462, and IGR J17480–2446 suggested an impurity parameter of the order of unity (Brown & Cumming 2009; Degenaar et al. 2011a; Page & Reddy 2013; Medin & Cumming 2014), consistent with expectations from molecular dynamics simulations (Horowitz et al. 2008). In fact, taking into account allowed ranges in mass, radius, and accretion rate, Brown & Cumming (2009) set an upper limit of $Q_{\text{imp}} \lesssim 10$ for KS 1731–260 and MXB 1659–29. The higher value that we find here could imply that the crust of EXO 0748–676 has a more impure (i.e., less organized) structure than the other neutron stars, although it is unclear why that would be the case. Moreover, the obtained value of Q_{imp} is sensitive to other model parameters.

If we allow for a higher mass-accretion rate, e.g., $\dot{M} = 1.2 \times 10^{17}$ g s $^{-1}$, the crust temperature rises and therefore we require a lower impurity parameter ($Q_{\text{imp}} = 20$), and less extra heat ($Q_{\text{extra}} = 0.35$ MeV nucleon $^{-1}$). This mass-accretion rate is higher than inferred from X-ray observations

($\dot{M} \simeq 3 \times 10^{16}$ g s $^{-1}$; e.g., Degenaar et al. 2011b; Díaz Trigo et al. 2011), but not implausible. There are large uncertainties in determining the accretion rate from X-ray observations, in particular for high-inclination systems such as EXO 0748–676 when part of the central X-ray source may be blocked from our line of sight, causing \dot{M} to be underestimated. Nevertheless, even for this higher accretion rate Q_{imp} remains considerably larger than found for the other sources. Another possible way of keeping the crust in EXO 0748–676 hot for a long time is residual accretion during quiescence.

4.3. On the Possibility of Quiescent Accretion

Our interpretation of the observations of EXO 0748–676 in the crustal heating/cooling framework relies on the assumption that accretion onto the neutron star stopped when the source transitioned to quiescence. It is not straightforward to test this hypothesis with observations. Low-level accretion may generate a thermal emission spectrum like that of a cooling neutron star (Zampieri et al. 1995; Soria et al. 2011). However, the measured temperature would then reflect that of the stellar surface that is continuously heated by residual accretion and masks the interior temperature of the neutron star. We therefore searched for signatures of quiescent accretion in EXO 0748–676.

X-ray monitoring with *Swift* has revealed X-ray flares in several quiescent neutron stars, e.g., XTE J1701–462, Aql X-1, Cen X-4, KS 1741–293, GRS 1741.9–2853, and SAX J1750.8–2900 (e.g., Bernardini et al. 2013; Degenaar & Wijnands 2009, 2013; Degenaar et al. 2012b; Fridriksson et al. 2011; Wijnands & Degenaar 2013; Coti Zelati et al. 2014). During these X-ray flares the XRT count rate increased for several days by a factor of $\simeq 2$ to even > 10 for some of these sources. A corresponding hardening of the X-ray spectrum is observed and suggests that these flares are possibly caused by a spurt of low-level accretion. EXO 0748–676 was monitored with *Swift* roughly once per month for $\simeq 10$ ks between 2008 and 2011. We did not detect any irregular X-ray variability or flaring events such as seen in other sources. Regular *Swift* monitoring has therefore not revealed any indications of ongoing low-level accretion in EXO 0748–676. However, accretion flares appear to be short-lived events (lasting \simeq days), and could therefore easily be missed (e.g., Degenaar & Wijnands 2009, 2013; Fridriksson et al. 2011; Wijnands & Degenaar 2013; Coti Zelati et al. 2014).

The first *Chandra* and *XMM-Newton* observations of EXO 0748–676 (obtained in 2008, within 2 months after the outburst end) both showed the presence of non-thermal emission, albeit contributing only $\lesssim 15\%$ to the total unabsorbed 0.5–10 keV flux (whereas this is $> 50\%$ in some other neutron stars such as SAX J1808.4–3658, *Swift* J1749.4–2807, and EXO 1745–248; e.g., Heinke et al. 2009; Degenaar & Wijnands 2012; Degenaar et al. 2012a). Optical spectroscopic and photometric observations performed shortly after the transition to quiescence hinted the presence of an accretion disk that could allow for continued accretion onto the neutron star (Bassa et al. 2009; Hynes & Jones 2009). However, optical spectroscopy and Doppler tomography performed one year later did not show evidence for an accretion disk any more (Ratti et al. 2012). Any contribution from non-thermal X-ray emission also remained low at this time (Section 3.1). Finally, there are no dips or other features in the quiescent X-ray light curves that might evidence the presence of a residual accretion stream or remnant disk (see also Díaz Trigo et al. 2011).

We conclude that there are no obvious signs of ongoing accretion in the quiescent state of EXO 0748–676, particularly

not $\gtrsim 1$ yr after the outburst ended. Given the optical signatures of a quiescent accretion disk and the presence of non-thermal X-ray emission we cannot exclude, however, that matter was falling onto the neutron star shortly after the outburst appeared to have ended.
