Observation of an Excited $B_c^{\pm}$ Meson State with the ATLAS Detector

G. Aad et al.*

(ATLAS Collaboration)

(Received 3 July 2014; published 21 November 2014)

A search for excited states of the $B_c^{\pm}$ meson is performed using 4.9 fb$^{-1}$ of 7 TeV and 19.2 fb$^{-1}$ of 8 TeV $pp$ collision data collected by the ATLAS experiment at the LHC. A new state is observed through its hadronic transition to the ground state, with the latter detected in the decay $B_c^{\pm} \rightarrow J/\psi \pi^{\pm}$. The state appears in the $m(B_c^{\pm} \pi^{\mp}) - m(B_c^{\mp}) - 2m(\pi^{\pm})$ mass difference distribution with a significance of 5.2 standard deviations. The mass of the observed state is $6842 \pm 4 \pm 5$ MeV, where the first error is statistical and the second is systematic. The mass and decay of this state are consistent with expectations for the second $S$-wave state of the $B_c^{\pm}$ meson, $B_c^{\pm}(2S)$.

DOI: 10.1103/PhysRevLett.113.212004

PACS numbers: 14.40.Nd

The $B_c^{\pm}$ meson was first observed by the CDF experiment in the semileptonic decay mode [1], and its hadronic decay mode was observed later by both the CDF [2] and the D0 [3] experiments. The $B_c^{\pm}$ meson has also been observed by the LHCb experiment in various decay modes [4]. Excited states of the $B_c^{\pm}$ meson have not previously been observed. The spectrum and properties of the $B_c^{\pm}$ family are predicted by nonrelativistic potential models, perturbative QCD, and lattice calculations [5]. Measurements of the ground and excited states through fully reconstructed channels will provide tests of the predictions of these models and ultimately the opportunity to extract information on the strong interaction potential.

The second $S$-wave state, $B_c^{\pm}(2S)$, is predicted to have a mass in the range 6835–6917 MeV [5]. The next $S$-wave state, $B_c^{\pm}(3S)$, is predicted to have a mass above the threshold for decay into a $BD$ meson pair. Both the $1S$ and $2S$ states have pseudoscalar ($0^-$) and vector ($1^-$) spin states that are predicted to differ in mass by about 20–50 MeV. Transitions between the spin states occur through soft photon radiation that escapes identification in ATLAS; the spin states cannot be separated by this analysis.

This Letter presents the observation of a new state whose mass is consistent with predictions for the $B_c^{\pm}(2S)$, the second $S$-wave state of the $B_c^{\pm}$ meson. The $B_c^{\pm}(2S)$ state is reconstructed in the decay to the $B_c^{\pm}$ meson and two oppositely charged pions, with the $B_c^{\pm}$ reconstructed through its decay to $J/\psi \pi^{\pm}$, $J/\psi \rightarrow \mu^+\mu^-$. The ATLAS Collaboration at the Large Hadron Collider (LHC) uses a general-purpose particle detector [6] consisting of several subsystems including the inner detector (ID), the electromagnetic and hadronic calorimeters, and the muon spectrometer (MS). Muon reconstruction at ATLAS makes use of both the ID and the MS.

Muons pass through the calorimeters and reach the MS if their momentum is above approximately 3 GeV. The inner detector features a three-component tracking system, consisting of two silicon-based detectors, the pixel detector and the microstrip semiconductor tracker (SCT), and the transition radiation tracker (TRT). ID tracks are reconstructed if their transverse momentum $p_T$ [7] is greater than 400 MeV and the magnitude of their pseudorapidity $|\eta|$ is less than 2.5. Muon candidates are formed from a standalone MS track that is matched to an ID track [8]. In this analysis the MS is only used to identify muons, while their momentum is measured using the ID information only.

The trigger system [9] comprises three levels: the hardware-based Level-1 trigger and the High-Level Triggers (HLT), consisting of the Level-2 trigger and the Event Filter (EF). The Level-1 trigger uses resistive plate chambers (RPC) and thin gap chambers (TGC) to trigger muons in the pseudorapidity ranges of $|\eta| < 1.05$ and $1.05 < |\eta| < 2.5$, respectively. One or more regions of interest identified by the Level-1 muon trigger seed the HLT muon online reconstruction algorithms, where the responses from both the ID and the MS are combined. For this analysis the HLT muon selection for the $J/\psi$ requires two muons, respectively, $\mu_1$ and $\mu_2$, originating at a common vertex, with the invariant mass of the muon pair lying between 2.5 and 4.3 GeV. The individual muon $p_T$ thresholds are $p_T(\mu_1) > 6$ GeV and $p_T(\mu_2) > 4$ GeV.

This study uses $pp$ collision data collected in the years 2011 ($\sqrt{s} = 7$ TeV) and 2012 ($\sqrt{s} = 8$ TeV) by the ATLAS experiment. The data sets correspond to an integrated luminosity of 4.9 and 19.2 fb$^{-1}$, respectively. The luminosity estimate has an uncertainty of 1.8% in 2011 [10] and 2.8% in 2012.

To improve the resolution, peaks are sought in the distribution of the variable $Q = m(B_c^{\pm} \pi \pi) - m(B_0^{\mp}) - 2m(\pi^\pm)$, where $m(B_c^{\pm})$ is the offline reconstructed invariant

mass of the $B^\pm_c$ candidate, $m(B^\pm_c\pi)$ is the invariant mass of the $B^\pm_c$ candidate combined with two charged pion candidates, and $m(\pi^\pm)$ is the charged pion mass [11]. The $B^\pm_c$ candidates are reconstructed through the decay $B^\pm_c \to J/\psi(\mu^+\mu^-)\pi^\pm$. Since hadronic decays of excited $B$-meson states have no observable displacement from the $pp$ interaction point, these candidates are then combined with two charged pion candidates, both originating at the corresponding $pp$ interaction point. The mass difference $(Q)$ distribution is formed and analyzed in the range 0–700 MeV.

The $B^\pm_c$ selection criteria for the events are optimized separately for 7 and 8 TeV data using the corresponding Monte Carlo (MC) samples, produced in the ATLAS simulation framework [12,13]. Differences between the 7 and 8 TeV selection criteria are due to the higher $\sqrt{s}$ and the number of simultaneous $pp$ interactions per bunch crossing, hereafter called pileup. The increase in the $B^\pm_c$ production cross section between the 7 and 8 TeV MC samples is approximately 3%.

The PYTHIA 6 and 8 MC generators [14,15], tuned for the LHC conditions [16], are used along with a dedicated PYTHIA extension for $B^\pm_c$ meson production, based on calculations from Ref. [17]. The following MC samples are used to optimize the event selection criteria (charge conjugates implied): $B^+_c$ decay modes $J/\psi\pi^+\pi^-$, $J/\psi K^+$, $J/\psi \rho^+ (\rho^+ \to \pi^0 \pi^+)$, $J/\psi \mu^+\nu$, $J/\psi \pi^0\pi^+$, $J/\psi \pi^+\pi^-\pi^+$, as well as $J/\psi X$ produced inclusively or from $b\bar{b}$. The MC simulated events are treated in exactly the same way as the collision data, and the same analysis selections are always applied. The exclusive ($B^+_c$) channels are generated with PYTHIA 6, and inclusive ($J/\psi X$) channels are generated with PYTHIA 8.

This analysis involves several steps. First the $J/\psi$ candidates are formed as described below. Then a pion track candidate from the same vertex is added to form a $B^\pm_c$ meson candidate. Finally, the $B^\pm_c$ (28) candidates are formed by adding two pion candidates originating at the primary vertex (PV); the selection of the primary vertex is defined below.

The $J/\psi$ candidates are reconstructed from pairs of oppositely charged muons. These pairs are fitted to a common vertex with the procedure described in Ref. [18]. The following requirements are applied to each $J/\psi$ candidate:

(i) The $p_T$ of the higher-$p_T$ muon candidate must be above 6 GeV, and the $p_T$ of the lower-$p_T$ muon candidate must be above 4 GeV; these are approximately the $p_T$ values for which the trigger is fully efficient. (ii) The $J/\psi$ vertex fit chi-square per degree of freedom $\chi^2/NDOF < 15$ (this selection keeps more than 99.9% of the candidates, and is included only to remove spurious dimuon combinations). (iii) The invariant mass resolution of the $J/\psi$ depends on the direction of the muons, with more forward candidates showing poorer resolutions. The sample is split into three categories and selection requirements are optimized for each of them: (i) both muons have $|\eta| < 1.05$, (ii) one muon has $|\eta| < 1.05$ and the other one has 1.05 < |\eta| < 2.5, (iii) both muons have 1.05 < |\eta| < 2.5.

The invariant mass $m(\mu^+\mu^-)$ is calculated from the track parameters adjusted by the common-vertex fit to be in a three standard deviation ($\pm 3\sigma$) mass window around the world average mass $m(J/\psi)$ [11], where the $J/\psi$ reconstructed width $\sigma$ varies in the range 40–90 MeV depending on muon reconstruction precision in different regions of pseudorapidity and on the data-taking period.

Selection requirements for the $B^\pm_c$ were chosen by maximizing $S/\sqrt{S+B}$ using MC events. Here, $S$ is the number of signal events and $B$ refers to the number of background MC events scaled according to the production cross section. The production cross sections are taken from the MC generators’ predictions. The optimization has been carried out separately for the two different data sets.

The pion candidate from the $B^\pm_c$ is required to have $p_T > 4$ GeV. Hit requirements in the pixel detector and SCT are imposed on all tracks to ensure a reliable impact parameter reconstruction.

$B^\pm_c$ candidates are reconstructed by fitting two muon tracks from the $J/\psi$ candidate together with a pion candidate track to a common vertex. The invariant mass of the two muons is constrained to the world average of $m(J/\psi)$. The yields per unit of integrated luminosity, and the central values of the dimuon invariant mass distributions, are verified to be consistent within each data set.

A significant part of the combinatorial background consists of real $J/\psi$ candidates combined with candidate pions that are not associated with a $B^\pm_c \to J/\psi \pi^\pm$ decay. This background is reduced by imposing a lower cut on $d_0/\sigma(d_0)$: $d_0$ here represents the projection of the pion track impact parameter relative to the primary vertex onto the transverse plane, and $\sigma(d_0)$ is the track-by-track uncertainty on $d_0$. Pion candidates are required to have $d_0/\sigma(d_0) > 5$ for 7 TeV data and $> 4.5$ for 8 TeV data. In 7 TeV data the PV is defined as the collision vertex with the highest summed scalar $p_T^2$ of its constituent tracks. In 8 TeV data—the data collected with higher pileup—the PV is identified as the vertex closest in three dimensions to the reconstructed decay vertex of the $B^\pm_c$ candidate. All reconstructed $B^\pm_c$ candidates are also required to satisfy the following selection criteria:

(i) The $J/\psi \pi$ vertex fit $\chi^2/NDOF < 2$ for 7 TeV and $< 1.5$ for 8 TeV data. (ii) The $p_T$ of the $B^\pm_c$ candidate must be above 15 GeV for 7 TeV and above 18 GeV for 8 TeV data.

Figure 1 shows the invariant mass distributions for the $B^\pm_c$ candidates for 7 TeV data and 8 TeV data in the mass range 5620–6820 MeV. Both distributions are fitted separately using an extended unbinned maximum likelihood fit, with a Gaussian function modeling the signal and an exponential modeling the background shape. The various
additional selection requirement is applied to the results of the fits are summarized in Table I. The fitted mass
have negligible contribution to the background shape. The

\[ m_B \rightarrow J/\psi \pi^\pm \ \text{candidates in 7 TeV data (top) and in 8 TeV data (bottom). The data are represented by the}
\]

exclusive \( B_{c}^\pm \) decay modes mentioned above are shown to have negligible contribution to the background shape. The
results of the fits are summarized in Table I. The fitted mass
values are consistent with the world average for the \( B_{c}^\pm \)
mass [11]. The signal yield per fb\(^{-1}\) of the \( B_{c}^\pm \) is lower in
8 TeV data due to the harder \( p_T \) requirements. The stability
of the \( B_{c}^\pm \) yield was checked through its normalization to
\( B_{c}^\pm \rightarrow J/\psi K^\pm \) decays that were reconstructed with similar
requirements.

The reconstruction of the excited state candidates uses the \( B_{c}^\pm \) ground state candidates within \( \pm 3\sigma \) of the fitted mass value of the corresponding data set. These candidates are combined as described below with two pion candidate tracks associated with the corresponding primary vertex. The \( p_T \) threshold of the pion candidates is 400 MeV. No additional selection requirement is applied to the \( B_{c}^\pm (2S) \)
pion candidates. The three tracks from the secondary vertex and the two tracks from the primary vertex are refitted simultaneously with the following constraints given by the

decay topology: the refitted triplet of the \( B_{c}^\pm \) tracks and the
pair of PV pion tracks must intersect in two separate \( B_{c}^\pm \)
and \( B_{c}^\pm (2S) \) vertices. The invariant mass of the refitted
muon tracks is constrained to the \( J/\psi \) world average mass, and the combined momentum of the refitted \( B_{c}^\pm \) tracks must
point to the \( B_{c}^\pm (2S) \) vertex. When multiple \( B_{c}^\pm (2S) \)
candidates are found in the same event, the one with the
best \( \chi^2 \) value returned by the fitter is kept as an excited state
candidate. Wrong-charge combinations \( (B_{c}^\pm \pi^+ \pi^- \) and
\( B_{c}^\pm \pi^- \pi^-) \) are kept separately for comparison with the
combinatorial background shape in the right-charge combinations (oppositely charged pion pairs).

Figure 2 shows the mass difference distribution
\[ m(B_{c}^\pm \pi^\pm \pi^-) - m(B_{c}^\pm) - 2m(\pi) \]
for the right-charge combinations \( B_{c}^\pm \pi^+ \pi^- \) as well as the wrong-charge combinations.

A structure is observed in the mass difference distribution. In order to characterize it, an unbinned maximum
likelihood fit to the right-charge combinations is performed. The fit includes a third-order polynomial to model the
background and a Gaussian function for the structure. The background shape resulting from the fit is verified to be
consistent with the wrong-charge combinations (which are not used to constrain the model in the right-charge fit) by
fitting the same shape to them, with the normalization as the only free parameter.Alternative models for the signal
and the background parametrizations are studied as sources of systematic uncertainty. A Breit-Wigner contribution was
tested in convolution with the Gaussian function and was found to be negligible, implying that the natural width of
the structure is small relative to the detector resolution. The resulting fit parameters (with statistical uncertainties only),
including the background and a Gaussian function for the structure. The background shape resulting from the fit is verified to be
consistent with the wrong-charge combinations (which are not used to constrain the model in the right-charge fit) by
fitting the same shape to them, with the normalization as the only free parameter. Alternatively, models for the signal
and the background parametrizations are studied as sources of systematic uncertainty. A Breit-Wigner contribution was
tested in convolution with the Gaussian function and was found to be negligible, implying that the natural width of
the structure is small relative to the detector resolution. The resulting fit parameters (with statistical uncertainties only),
along with the distributions of the wrong-charge combinations \( (B_{c}^\pm \pi^\pm \pi^-) \) are shown in Fig. 2. The wrong-
charge combinations, are normalized to the same yield as the right-charge background.

The relative \( B_{c}^\pm (2S)/B_{c}^\pm \) yield ratio is verified to be statistically consistent between the 7 and 8 TeV data.

The fit finds the peak at a mass difference \( (Q) \) value of
\[ 288.2 \pm 5.1 \ \text{MeV in the 7 TeV data and 288.4 \pm 4.8 \ \text{MeV}
\] in the 8 TeV data. The fit yields \[ 22 \pm 6 \ \text{signal events in the}
7 TeV data and 35 \pm 13 \ \text{events in the 8 TeV data. The Gaussian}
width of the structure is found to be \[ 18.2 \pm 3.8 \ \text{MeV in the 7 TeV data and 17.6 \pm 4.0 \ \text{MeV in the}
8 TeV data. All uncertainties mentioned in this paragraph do not include systematic uncertainties.}

There are two dominant sources of systematic uncertainty on the position of the peak. One comes from the
The contribution from the uncertainty on the pion momentum procedure and estimated below to be about 3.6 MeV. The mass difference distribution itself. The uncertainty on the mass difference distribution is largely canceled in the mass difference distribution. The other involves systematic uncertainties in the fit of the mass difference distribution and is largely canceled in the mass difference distribution. The solid line is the projection of the results of the unbinned maximum likelihood fit to all candidates in the range 0–700 MeV. The dashed line is the projection of the background component of the same fit.

Within the uncertainties, the mass of the resonance corresponding to the observed structure is consistent with the predicted mass of the \(B_c^+ (2S)\) state.

The various sources of systematic uncertainty are treated as uncorrelated. The total averaged systematic uncertainty propagated to the mass value of the new structure is approximately 4.1 MeV.

The significance of the new structure is evaluated with pseudoexperiments. A large number of background-only mass difference distributions are generated. Parameters of the generation are taken from the fit with their uncertainties to account for systematic effects. The background shape is scaled to the observed number of events. The mean mass value of the signal contribution is left free to vary within the theoretically motivated range (6835–6917 MeV) to evaluate the “look-elsewhere effect” [19]. The significance is calculated as the fraction of the pseudoexperiments in which the difference of the logarithms of fit likelihoods \(\Delta \ln L\) with and without signal is larger than in the data. In terms of standard deviations the significance of the observation is 3.7\(\sigma\) in the 7 TeV data and 4.5\(\sigma\) in the 8 TeV data. For the combined 7 and 8 TeV data set the total significance of the observation is found to be 5.2\(\sigma\). The significance of the observation, obtained by fixing the mean value of the signal component, is 5.4\(\sigma\).

In conclusion, the distribution of the mass difference \(Q = m(B_c^{+}\pi\pi^-) - m(B_c^+) - 2m(\pi^+)\) for events with the \(B_c^+\) meson reconstructed in its decay to \(J/\psi\pi^\pm\) has been investigated in \(pp\) collisions at the LHC using the ATLAS detector. The analysis is based on an integrated luminosity of 4.9 (19.2) fb\(^{-1}\) of \(pp\) collisions at a center-of-mass energy of 7 (8) TeV. A new state is observed at \(Q = 288.3 \pm 3.5 \pm 4.1\) MeV (calculated as the error weighted mean of the 7 and 8 TeV mass values) corresponding to a mass of 6842 \(\pm 4 \pm 5\) MeV, where the first error is statistical and the second is systematic. The significance of the observation is 5.2\(\sigma\) with the look-elsewhere effect taken into account, and the local significance is 5.4\(\sigma\).

Within the uncertainties, the mass of the resonance corresponding to the observed structure is consistent with the predicted mass of the \(B_c^+ (2S)\) state.

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions, without whom ATLAS could not be operated efficiently.

[7] ATLAS uses a right-handed coordinate system with its origin at the nominal interaction point (IP) in the center of the detector and the z axis along the beam line. The x axis points from the IP to the center of the LHC ring, and the y axis points upward. Polar coordinates (r, θ) are used in the transverse (x, y) plane, ϕ being the azimuthal angle around the beam pipe. The pseudorapidity is defined in terms of the polar angle θ as $$\eta = - \ln \tan(\theta/2).$$
