Search for new resonances in $W\gamma$ and $Z\gamma$ final states in $pp$ collisions at $\sqrt{s} = 8$ TeV with the ATLAS detector

ATLAS Collaboration*

**Abstract**

This Letter presents a search for new resonances decaying to final states with a vector boson produced in association with a high transverse momentum photon, $VV\gamma$, with $V = W(\to \ell\nu)$ or $Z(\to \ell^+\ell^-)$, where $\ell = \mu$ or $e$. The measurements use 20.3 fb$^{-1}$ of proton–proton collision data at a center-of-mass energy of $\sqrt{s} = 8$ TeV recorded with the ATLAS detector. No deviations from the Standard Model expectations are found, and production cross section limits are set at 95% confidence level. Masses of the hypothetical $\sigma_T$ and $\alpha_T$ states of a benchmark Low Scale Technicolor model are excluded in the ranges $[275, 960]$ GeV and $[200, 700]$ GeV, respectively. Limits at 95% confidence level on the production cross section of a singlet scalar resonance decaying to $Z\gamma$ final states have also been obtained for masses below 1180 GeV.

**1. Introduction**

The search for diboson resonances is an essential step in exploring the source of Electroweak Symmetry Breaking (EWSB). The observation of a Higgs boson decaying to $\gamma\gamma$, $ZZ$ and $W^+W^−$ final states, reported by the ATLAS and CMS Collaborations [1,2], represents a milestone in particle physics history. However, the precise nature of the observed Higgs boson is not well known, and a dynamical mechanism of EWSB and fermion mass generation may yet involve a variety of heavy bosons of spin-0 or spin-1.

This Letter presents a search for narrow scalar and vector heavy resonances decaying to $W\gamma$ or $Z\gamma$ final states, where the $W$ and $Z$ bosons decay to leptons ($\ell$ or $\mu$). The existence of a new vector or scalar resonance coupling to a boson pair $W\gamma$ or $Z\gamma$ is predicted by many physics scenarios, including various new physics models with scalar particles [3,4] and vector particles [5].

The Low Scale Technicolor (LSTC) [5] model is used as a benchmark model for the search for spin-1 resonances decaying to $W\gamma$ and $Z\gamma$ final states explored in this paper. The discovery of a Higgs boson, with its parameters in agreement with the Standard Model (SM) predictions, does not exclude the full phase space of the LSTC model, and the basic phenomenology would remain valid for a Technicolor model with a light composite Higgs boson. To minimize the model dependence of the search results, the signal cross section is measured within a well defined fiducial region. The predicted new bound states of the lightest doublet of technifermions, the technimesons $\sigma_T$, $\omega_T$, $\rho_T$, and $\pi_T$, generate a new phenomenology. The mass splittings between the technimesons are set to be as follows: $m_{\sigma_T} = m_{\omega_T} = m_{\rho_T} = \frac{1.1 \times m_{\rho_T}}{\sin^2\theta_W}$ and $m_{\rho_T} - m_{\pi_T} = m_W$ [6]. The decays of technimesons to technipions are therefore kinematically forbidden. The technimesons mostly decay to pairs of electroweak gauge bosons, the most abundant decay channels being $\omega_T \to Z\gamma$, $\sigma_T \to W\gamma$ and $\rho_T \to WZ, W\gamma$. These technimeson resonances are expected to be narrow, with typical values $\Gamma_T(\rho_T, \omega_T, \sigma_T) \approx 1$ GeV.

A phenomenological model describing a singlet scalar particle $\phi$ [7,8] is chosen as another benchmark in the search for spin-0 resonances decaying to $Z\gamma$. The neutral scalar could be composite, produced by a hypothetical new strong interaction. It could be the pseudo-Goldstone boson playing an important role in the dynamical EWSB. This low energy effective model is independent of the underlying dynamical details and its Lagrangian can be written as follows:

\[
\mathcal{L}_{\text{eff}} = c_g \frac{4\pi \alpha_t}{\Lambda} \phi G^a_{\mu \nu} G^{a\mu \nu} + c_W \frac{4\pi \alpha_{\text{em}}}{\Lambda \sin^2\theta_W} \phi W^a_{\mu \nu} W^{a\mu \nu} + c_B \frac{4\pi \alpha_{\text{em}}}{\Lambda \cos^2\theta_W} \phi B_{\mu \nu} B^{\mu \nu}.
\]  

(1)

Here $\alpha_t$ and $\alpha_{\text{em}}$ are, respectively, the couplings of the strong and electromagnetic interactions, $\Lambda$ is the cutoff scale and $\theta_W$ is the Weinberg angle. Moreover, $c_g$, $c_W$ and $c_B$ are the coupling coefficients between the scalar field $\phi$ and the gluon field strength $G^a_{\mu \nu}$, the $SU(2)$ field strength $W^a_{\mu \nu}$ and the $U(1)$ field strength $B_{\mu \nu}$, respectively. The scalar field $\phi$ interacts directly with the...
gauge boson pairs via the dimension-5 operators rather than via the loop-induced processes, and could lead to enhanced production and branching ratio to $Z\gamma$ if $\Lambda$ is in the TeV scale. No SM Yukawa interaction of $\phi$ with fermions is allowed so that there is no decay to $bb$ or $tt$ final states. The $W^+W^-$ and $ZZ$ decays of $\phi$ are suppressed compared with the SM Higgs boson.

Previous limits on new resonances decaying to $W\gamma$ and $Z\gamma$ final states from $pp$ and $pp$ production have been obtained at the Tevatron by the D0 Collaboration [9] and at the Large Hadron Collider (LHC) by the ATLAS Collaboration [10]. At ATLAS, the production of $a_T$ and $\omega_T$ for masses below 703 GeV and 494 GeV, respectively, was excluded within the LSTC benchmark parameters. The most stringent limits on LSTC have been set by the CMS Collaboration, excluding the production of $p_T$ for masses below $m_{p_T} < 1.14$ TeV, but using a slightly different choice of parameters.

2. ATLAS detector and data sample

The ATLAS detector [12] is composed of an inner tracker detector (ID) surrounded by a thin superconducting solenoid providing a 2 T axial magnetic field, electromagnetic (EM) and hadronic calorimeters (HC), and a muon spectrometer (MS) immersed in the magnetic field produced by a system of superconducting toroids. The ID consists of three subsystems: the pixel and silicon microstrip detectors cover the pseudorapidity range $|\eta| < 2.5$, while the transition radiation tracker, made of straw tubes, has an acceptance range of $|\eta| < 2.0$. The calorimeter system covers the range $|\eta| < 4.9$. The highly segmented electromagnetic calorimeter plays a crucial role in electron and photon identification. It is composed of lead absorbers with Liquid Argon (LAr) as the active material and spans $|\eta| < 3.2$. In the region $|\eta| < 1.8$, a pre-sampler detector using a thin layer of LAr is used to correct for the energy lost by electrons and photons upstream of the calorimeter. The hadronic tile calorimeter ($|\eta| < 1.7$) is a steel/scintillating-tile detector and is located directly outside the envelope of the barrel electromagnetic calorimeter. The end-caps and forward calorimeters use LAr as the active material, with copper (EM) and tungsten (HC) as absorber materials. The MS is composed of three large superconducting air-core toroid magnets of eight coils each, a system of three stations of high precision tracking chambers in the range $|\eta| < 2.7$, and a muon trigger system which covers $|\eta| < 2.4$. The precision measurement is ensured by monitored drift tubes and, at large pseudorapidities ($|\eta| > 2$), for the innermost layer, by cathode strip chambers. The muon trigger system is composed of resistive plate chambers in the barrel region ($|\eta| < 0.05$), and thin gap chambers in the end-cap ($1.05 < |\eta| < 2.4$).

The ATLAS trigger system has three distinct levels, L1, L2 and the event filter, where each trigger level refines the decisions made at the previous level. The data used for the present analysis were collected in 2012 from $pp$ collisions at a center-of-mass energy of 8 TeV at the LHC. The total integrated luminosity is 20.3 fb$^{-1}$ with an uncertainty of 2.8% [13]. Events are selected by triggers requiring at least one identified electron or muon. The transverse energy ($E_T$) threshold for the single-lepton trigger is 24 GeV. The lepton trigger efficiencies are measured using Z boson candidates as a function of the transverse momentum $p_T$ and $\eta$. The trigger efficiencies for the leptons are approximately 70% for muons with $|\eta| < 1.05$, 90% for muons in the range $1.05 < |\eta| < 2.4$ [14], and 95% for electrons in the range $|\eta| < 2.4$.

3. Signal and background simulated samples

Monte Carlo (MC) event samples, including a full simulation [15] of the ATLAS detector with GEANT4 [16], are used to compare the data to the signal and background expectations. All MC samples are simulated with additional $pp$ interactions (pile-up) in the same and neighboring bunch crossings.

The production and decay of neutral ($\omega_T \rightarrow Z\gamma$) and charged technimesons ($a_T \rightarrow W\gamma$) in the LSTC model are handled by the PYSHERA6.426 generator [17]. The following parameters are used in the event generation: number of technicolors $N_C = 4$; techniquark charges $Q_U = 1$ and $Q_D = 0$ for the $Z\gamma$ final state and $Q_U = 1/2$ and $Q_D = -1/2$ for the $W\gamma$ final state. With this parameterization of the techniquark charges, the dominant contribution to the $W\gamma$ final state is from $a_T$ decay. By removing the $p_T$ contribution, the model dependence that could result from having two nearby peaks in the benchmark signal is further reduced. The size of the mixing angle between the technipions and the electroweak gauge boson longitudinal component is set to 1/3. As stated in the introduction, the mass splittings between the technimesons are set to: $m_{p_T} = m_{a_T}/1.1$, and $m_{p_T} - m_{\phi_T} = m_{\gamma}$. Simulations of the signals for singlet scalar particles are generated using MADGRAPH5 [18] interfaced to PYTHIA8 [19] for parton shower and fragmentation processes. The generation uses the leading-order (LO) parton distribution function (PDF) set MSTW2008LO [20]. Since the kinematic distribution of the $Z\gamma$ decay of a scalar boson is determined by its spin and CP properties in the narrow-width approximation, the gluon–gluon fusion production and the decay are simulated by using the SM Higgs process in MADGRAPH5, fixing the resonance width to 5.75 MeV.

The cross section of the singlet scalar process $gg \rightarrow \phi \rightarrow Z\gamma$ is calculated by choosing two sets of coupling parameters in Eq. (1). In the parameter set (a), the coupling coefficients are set to $c_{\gamma} = c_{\gamma} = -c_{\phi} = 1/4\sqrt{3}$, as suggested by naive Dimensional Analysis (NDA) [21]. Here, the relative phases are chosen to enhance the $Z\gamma$ coupling. If a large new color number $N_c = 4$ of the underlying strong dynamics is considered in NDA [22,23], and larger couplings with the electroweak gauge bosons are assumed [8], then larger values of the coefficients can also be possible, depending on the underlying theory. Thus another parameter set (b) is selected as follows: $c_{\gamma} = 1/2\sqrt{3}$, $c_{\phi} = -c_{\phi} = 1/\sqrt{3}$. In both parameterizations, the $Z\gamma$ decay rate is dominant over the $\gamma\gamma$ decay rate. The underlying dynamics scale is set to $\Lambda = 6$ TeV, motivated by the Higgs boson couplings measurements [24,25]. The width of the singlet scalar for each of set (a) and (b) is well below the experimental resolution over the full mass range studied.

The main background processes, SM $pp \rightarrow e^+e^-\gamma$ and $pp \rightarrow e\gamma\gamma$ production, are modeled using the SHERPA (1.4.1.0) generator [26]. An invariant mass cut of $m(e^+e^-) > 40$ GeV is applied at the generator level when simulating the $pp \rightarrow e^+e^-\gamma$ process. The CTEQ [27] PDF is used for samples generated with SHERPA. In the $W\gamma$ analysis, the $Z(e^+e^-)$ and $Z(\tau^+\tau^-)$ backgrounds are modelled with PYTHIA8. The final state radiation of photons from charged leptons is treated in PYTHIA8 using PHOTOS. TAUOLA [12.09] [28] is used to model $\tau$ lepton decays. Events with one or more hard photons at the generator level $(p_T > 10$ GeV) in $Z(e^+e^-)$ and $Z(\tau^+\tau^-)$ MC simulations are removed, in order to avoid overlaps with $Z\gamma$ MC samples. In the $Z\gamma$ analysis, $Z(e^+e^-)$ and $Z(\tau^+\tau^-)$ MC samples are used to cross check the data-driven $Z +$ jet background estimation.
Photon candidate reconstruction relies on clustered energy deposits in the EM calorimeter with $E_T > 40$ GeV in the range $|\eta| < 2.37$ (excluding the calorimeter transition region $1.37 < |\eta| < 1.52$). Clusters without matching tracks are directly classified as unconverted photon candidates. Clusters that are matched to tracks which originate from reconstructed conversion vertices in the ID or to tracks consistent with coming from a conversion are considered as converted photon candidates. Both unconverted and converted candidates are used in the present analysis. Tight requirements on the shower shapes [35] are applied to suppress the background from multiple showers produced in meson (e.g. $\pi^0$, $\eta'$) decays. To further reduce this background, a photon isolation requirement $E_T^{\text{iso}} > 4$ GeV is applied. The isolation variable $E_T^{\text{iso}}$ is the total transverse energy recorded in the calorimeters within a cone of $\Delta R = 0.4$ around the photon position excluding the energy deposit of the photon itself. The value of $E_T^{\text{iso}}$ is corrected for leakage from the photon energy cluster core into the isolation cone and for contributions from the underlying event and pile-up [35,37].

Jets are reconstructed from calibrated topological clusters built from energy deposits [12] in the calorimeter using the anti-$k_T$ jet clustering algorithm [38] with radius parameter $R = 0.4$. The selected jets are required to have $p_T > 25$ GeV with $|\eta| < 4.5$, and to be well separated from the lepton and photon candidates ($\Delta R(e/\mu/\gamma/\text{jet}) > 0.3$).

The $W\gamma$ final state has missing transverse momentum, $E_T^{\text{miss}}$ [39], due to the undetected neutrino from the $W$ boson decay. Its magnitude and direction are measured from the vector sum of the transverse momentum vectors associated with clusters of energy reconstructed in the calorimeters with $|\eta| < 4.9$. A correction is applied to the energy of those clusters that are associated with a reconstructed physical object (jet, electron, $\tau$-lepton, photon). Reconstructed muons are also included in the sum, and any calorimeter energy deposits associated with them are excluded to avoid double counting.

5. $W\gamma$ and $Z\gamma$ event selection

The $e\gamma$ candidate events are selected by requiring exactly one lepton with $p_T > 25$ GeV, at least one photon with $E_T > 40$ GeV and $E_T^{\text{miss}}$ above 35 GeV. In addition, the transverse mass\footnote{The transverse mass is defined as $m_T = \sqrt{2p_T(E - E_T^{\text{miss}})(1 - \cos\Delta\phi)}$, where $\Delta\phi$ is the azimuthal separation between the directions of the lepton and the missing transverse momentum vector.} of the lepton-$E_T^{\text{miss}}$ system is required to be greater than 40 GeV. A Z-veto requirement is applied in the electron channel of the $W\gamma$ analysis by requiring that the electron-photon invariant mass be not within 15 GeV of the $Z$ boson mass. This is used to suppress the background where one of the electrons from the $Z$ boson decay is mis-identified as a photon.

The $e^+e^-\gamma$ candidates are selected by requiring two oppositely charged same-flavor leptons with an invariant mass between 65 and 115 GeV, and at least one photon with $E_T > 40$ GeV. For $\mu^-\mu^-\gamma$, at least one of the two muons must be reconstructed both in the ID and the MS. If more than one $Z$ candidate is found in the same event, the one with mass closest to the $Z$ mass is retained.

In both the $W\gamma$ and $Z\gamma$ analyses, a selection requirement $\Delta R(e,\gamma) > 0.7$ is applied to suppress the contributions from photons radiated from the selected leptons. If more than one photon passes all of the selection criteria, the one with the highest $p_T$ is selected.
Table 1
Total number of events passing the $W/Z\gamma$ selection requirements in the data, and expected number of SM background events in the $e\nu\gamma$, $\mu\nu\gamma$, $e^+e^-\gamma$ and $\mu^+\mu^-\gamma$ final states. The first uncertainty is statistical and, when present, the second uncertainty shows an estimate of the systematic effects. The systematic uncertainty is only presented for $W+$ jets and $\gamma+$ jets background in $W\gamma$ analysis, and for $Z+$ jets background in $Z\gamma$ analysis, since the uncertainty on these background estimates dominates the uncertainty of the total background estimate. The "other backgrounds" include contributions from single top, $WW$ and $WZ$ production.

Fig. 1. Three-body transverse mass distribution for the $e\nu\gamma$ (a) and $\mu\nu\gamma$ (b) final states. The background-only fit to the data and the one standard deviation uncertainty band are shown. The significance (see text for details) as a function of $m_T^{\gamma\gamma\gamma}$ in the lower panel includes only statistical uncertainties. The expected signal for a resonance mass of 600 GeV is superimposed.

6. Analysis strategy

A search for a signal is performed with an unbinned maximum likelihood fit of the mass spectra of the $\ell\nu\gamma$ and $\ell^+\ell^-\gamma$ systems. In order to select and validate the probability density function used to model the background shape, a study of the background composition is also performed. In the final results, the background normalization and shape are extracted by performing a signal-plus-background maximum likelihood fit directly to the data spectrum.

7. Study of the background composition

The composition of the backgrounds affecting the $e\nu\gamma$ and $\ell^+\ell^-\gamma$ searches are studied by using a combination of simulation and data-driven methods. The dominant contribution is the SM $V\gamma$ production, then come other processes, like $V+$ jets, $\gamma+$ jets, $t\bar{t}$ and other diboson final states, such as $WW$ and $WZ$. The SM $V\gamma$ backgrounds are estimated using SHERPA MC samples. A control region is defined to validate the MC modeling. The events in the control regions are selected by imposing the nominal event selection criteria, except that the photon $E_T^{\gamma}$ is required to be between 15 and 40 GeV. The comparison of the relevant kinematic distributions, such as the transverse momenta of the leptons and photons and the transverse missing energy corresponding to the undetected neutrino, in the control regions shows that the $V\gamma$ background is well modeled by the MC simulation. The backgrounds estimated from data are $Z/W+$ jets and $\gamma+$ jets in the $\ell\nu\gamma$ final state, and $Z+$ jets in the $\ell^+\ell^-\gamma$ final state. The data-driven backgrounds are estimated by using a two-dimensional sideband method, as described in Ref. [40]. The remaining backgrounds, i.e. $t\bar{t}$, single top, $WW$, $WZ$ and $ZZ$ are estimated with MC simulations.

The background prediction obtained in all four final states is shown in Table 1. The distribution of the $W\gamma$ system three-body transverse mass for the selected $W\gamma$ events is shown in Fig. 1, while Fig. 2 presents the $Z\gamma$ invariant mass distribution. Here, data are compared to the sum of the SM expected backgrounds and show fair agreement. The significance, shown as a function of the mass in the lower panels, only includes statistical uncertainties and is defined as the z-value between the data points and the fit expectation, which is the deviation at the right of the mean of a Gaussian distribution, expressed in units of standard deviations, as described in Ref. [41]. The event rate in the high mass region has a significance below three standard deviations, and is attributed to a statistical fluctuation.

The $W\gamma$ system three-body transverse mass is defined as:

$$m_T^{W\gamma} = \left(\sqrt{m_T^\gamma + |p_T(\gamma) + p_T(\gamma')|^2 + \Delta E_T^{\text{miss}}}\right)^2$$

$$- |p_T(\gamma) + p_T(\gamma') + \Delta E_T^{\text{miss}}|^2.$$  \hspace{1cm} (2)
8. Fit model and statistical methods

The signal and background parameterizations have been chosen to best describe the mass distribution shapes of, respectively, fully simulated MC samples and a mixture of MC samples and data-driven estimates. The fit to data takes into account all systematic uncertainties, discussed in Section 8.4.

8.1. Background modeling

All the mass distributions, shown in Figs. 1 and 2, have a broad maximum in the low mass region due to the kinematic cuts used. The shape of the SM background is thus parameterized only for masses larger than 180 GeV.

A probability density function is chosen to describe the expected SM background mass distribution for the range, between 180 GeV and 1.6 TeV. The variation of the background composition, within systematic uncertainties, presented in Section 7 is also taken into account in evaluating the background parameterization systematics. For both the Wγ and Zγ final states, the probability density function best describing the SM background distribution, in the chosen range, is found to be the sum of two exponentials. The impact of the choice of the background model on the final result has been studied, as discussed in Section 8.4.

The results of the unbinned fit to the data can be seen as the solid curve on each of the mass spectra in Figs. 1 and 2. A good description of data is found, and the Pearson’s χ² per degree of freedom obtained for the background-only fit is close to unity for all distributions.

8.2. Signal modeling

The parameterizations of the signal shapes have been obtained from the benchmark signal MC samples. For all W/Zγ spin-1 and Zγ spin-0 resonances considered, the signal mass distribution is described by the sum of a Crystal-Ball function [CB] [42–44], which reproduces the core mass resolution plus a non-Gaussian tail for low mass values, and a small wider Gaussian component that takes into account outliers in the mass distribution. The mean value of the CB and the Gaussian are chosen to be the same.

For simulated events, the mean fitted mass is found to be within 2 GeV of the generated resonance mass for the Zγ final state. At the reconstruction level, the full width at half maximum of the Zγ signal grows approximately linearly from 7 GeV to 38 GeV in the electron channel, and from 7 GeV to 100 GeV in the muon channel, for masses generated between 200 GeV and 1.6 TeV. The full width at half maximum of the Wγ transverse mass also grows approximately linearly, and goes from 50 GeV to 100 GeV in the electron channel, and from 45 GeV to 190 GeV in the muon channel, for masses generated between 200 GeV and 1.6 TeV. These widths are completely dominated by reconstruction effects, since we assume the hypothetical signals to be narrow.

8.3. Statistical method

The search is conducted by performing a scan of the m_{Zγ} and \(m_{Wγ}\) distributions using a probability density function describing both the background shape and a signal peak at a given mass. The step size used in the scan is 20 GeV for the Wγ channel and 10 GeV for the Zγ channel. The difference in the scan step takes into account the different resolutions of a hypothetical peak in the two channels. The scan starts at a signal mass of 275 GeV for the Wγ final state, and of 200 GeV for the Zγ final state, and goes up to 1600 GeV. Each fit is performed in a mass range of [180, 1600] GeV for both Zγ and Wγ final states, in order to ensure that there are enough events in the sidebands of a hypothetical signal peak.

The background normalization and the two exponential coefficients of the SM background probability density function are free to vary in the fit. The parameters of the signal probability density functions are fixed to their nominal values from fits to the MC signal model, except for the normalization of the signal and for the nuisance parameters that account for the systematic uncertainties on the signal event rate and resolution, described below. The systematic uncertainty related to the choice of parameterization for the background, on the other hand, has been estimated by testing different parameterizations and verifying that the extracted background and signal yields do not vary significantly, and was found to be negligible with respect to the other systematic and statistical uncertainties considered.

The signal yield, \(N_S\), depends on the parameter of interest of the fit, i.e. the signal fiducial cross section \(\sigma_{\text{Fid}}\) at a given signal mass, as follows:

\[
N_S = \sigma_{\text{Fid}} \cdot \varepsilon_{\text{Reco}} \cdot \int L dt,
\]

where the factor \(\varepsilon_{\text{Reco}}\) is the signal reconstruction efficiency, defined as the number of reconstructed signal events passing the full
Table 2
Definition of the fiducial region at the particle generator level. Here $p_T^\nu$ is the transverse momentum of the neutrino from the $W$ boson decay; $N_l$ is the number of leptons per event; $\epsilon_P^\ell$ is the photon isolation fraction.

Event selection divided by the number of events generated in the fiducial region defined in Table 2. The signal reconstruction efficiency has been estimated by using signal MC simulated samples, and accounts for effects due to the detector resolution on the lepton and photon transverse momentum and energies, and on the missing transverse energy. The parameter $\epsilon_P^\ell$ in the table is defined at particle level as the sum of the energy carried by final state particles in a $\Delta R = 0.4$ cone around the photon direction (not including the photon) divided by the energy carried by the photon. To account for the effect of final-state QED radiation, the energy of the generated lepton at particle level is defined as the energy of the lepton after radiation plus the energy of all radiated photons within a $\Delta R = 0.1$ cone around the lepton direction. The $\sigma_{fid}$ parameter is the same for both muon and electron channels in each final state, and is thus determined by simultaneously performing the fit in the two channels, so that the results obtained are less sensitive to statistical fluctuations.

In order to test different hypothetical values of the parameter of interest, the test statistic based on the Profile Likelihood Ratio $\lambda(\sigma_{fid}; \theta)$ is used, where $\theta$ is the vector of nuisance parameters, defined in Ref. [45]. It is defined from the likelihood describing the probability density function of $m_T^{\ell\nu\gamma}$ and $m^{e^+e^-\gamma}$ under a signal-plus-background hypothesis and is a function of the parameter of interest and of the nuisance parameters related to the systematic uncertainties. The statistical tests are then performed on the $m_T^{\ell\nu\gamma}$ and $m^{e^+e^-\gamma}$ distributions combining the muon and electron channels in each final state.

The probability of the background-only hypothesis, or local $p_0$-value, is obtained by using a frequentist approach. The latter gives the probability that the background fluctuates to the observation or above. If no hint for a new physics signal is found, the data is interpreted by using a modified frequentist approach ($C_{L_u}$) [46] for setting limits. A fiducial cross section is claimed to be excluded at 95% CL when $C_{L_u}$ is less than 0.05.

8.4. Systematic uncertainties

Systematic uncertainties on the signal resonances are taken into account as nuisance parameters in the likelihood function used for the full signal and background model. Two different effects are evaluated for each source of systematic uncertainty, one for the signal event rate and one for the resolution of the signal. The rest of the parameters are kept fixed to their nominal value in the fit. Each systematic effect is investigated by propagating the corresponding uncertainty to the signal sample. These are computed separately for each of the simulated resonance mass points. The systematic uncertainties are summarized below for $m_{W\gamma} = 500$ GeV in the $Z\gamma$ channel and $m_{W\gamma} = 600$ GeV in the $W\gamma$ channel.

For the photon, systematic effects due to isolation, identification, energy resolution and energy scale are considered. The systematic uncertainties due to the photon reconstruction and identification are dominant. The total effect on the signal event rate is estimated to be 3.4% in all of the channels, and contributes up to 3 GeV, depending on the final state and channel, to the systematic uncertainty on the signal peak width.

The systematic effects due to the electron energy resolution and electron energy scale [47] are treated as fully correlated with the photon energy scale and resolution in the final states containing electrons ($e^+e^-\gamma$ and $e\nu\gamma$). The effects of the muon energy scale and muon energy resolution, lepton identification and trigger efficiency are also investigated. The total effect of the lepton reconstruction and identification on the signal event rate reaches 1.5% in the electron channels, and 1% in the muon channels. The effect on the peak width due to lepton reconstruction and identification amounts to 0.3 GeV or less.

Systematic effects due to the jet energy scale and resolution and the calibration of the missing transverse energy only have an impact on the $W\gamma$ final state. These are found to cause uncertainties in the event rate of about 0.9% and on the peak width of up to 0.2 GeV. The jet energy scale and resolution effects on the $Z\gamma$ final state are negligible.

Finally a systematic uncertainty on the resonance production rate due to the 2.8% uncertainty on the integrated luminosity [13] is considered.

The total systematic uncertainty on the event rate is found to be approximately 5%, adding all independent contributions in quadrature, for all the mass points in the two channels. The systematic uncertainty on the peak width is found to be approximately 1.5 (0.5) GeV for the $Z\gamma$ final state at $m_{W\gamma} = 500$ GeV in the electron (muon) channel, and 2.8 (1.1) GeV at $m_{W\gamma} = 600$ GeV in the $W\gamma$ final state, in the electron (muon) channel.

Since the SM backgrounds are determined using a fit to the data, uncertainties on the detector resolution and physics object reconstruction or identification have a negligible effect on the total background yield extraction. However, a systematic effect from the background modeling is investigated. The method considered consists of generating background-only “Asimov” datasets [45], and fitting them with the signal and background model in order to estimate the bias introduced on the fitted signal yield (“spurious signal”). In the $Z\gamma$ low mass region, it is found that the spurious signal reaches 25% of the statistical uncertainty on the total background yield, in the rest of the regions of all $Z\gamma$ and $W\gamma$ final states the spurious signal is below 10% and has a negligible impact. For these regions an additional systematic uncertainty is assigned, associating a nuisance parameter to the amount of spurious signal estimated in the above described procedure.

9. Results

The two largest deviations from the background-only configuration are observed, in the spin-1 search, at 1350 GeV for the $W\gamma$ final state, and at 350 GeV and 700 GeV for the $Z\gamma$ final state. Similarly, in the spin-0 search, the largest deviation is close to 350 GeV. The $p_0$-values are estimated to be greater than 0.01 in all cases, corresponding in all cases to a local significance below approximately 2.5$\sigma$. These small excesses, also visible in the mass spectra in Figs. 1 and 2, are at the level expected due to statistical fluctuations. No evidence of a new physics signal is found in the $W\gamma$ and $Z\gamma$ final states when analyzing the totality of the 8 TeV data collected by ATLAS in the mass ranges considered.

Therefore, 95% CL limits are set on the production of LSTC technimesons and composite scalars decaying to $W\gamma$ and $Z\gamma$ final

---

4 An Asimov dataset is defined as being a single representative dataset replacing the ensemble of simulated datasets.
Fig. 3. Observed limits in the fiducial region in the: $W\gamma$ final state as a function of $m_{\gamma}$ (a), $Z\gamma$ final state as a function of $m_{\gamma}$ (b) and $Z\gamma$ final state as a function of $m_{\phi} (c)$ obtained using the full 8 TeV ATLAS dataset. The black line is the observed limit. The dashed black line is the expected limit, the yellow and green bands are the one and two $\sigma$ uncertainties on the expectation. The red lines in (a) and (b) are the theoretical cross sections for the LSTC benchmark models considered. The blue line and magenta line in (c) show the theoretical cross sections for the benchmark composite scalar model with the parameter set (a) and (b), respectively. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

10. Conclusions

This paper describes the results of searches with the ATLAS detector for LSTC technimesons and composite scalar particles decaying to $V\gamma$ final states. The observed data prove to be consistent with the SM background expectations. Using the LSTC benchmark model, the production of $\sigma_t$ is excluded up to $m_{\sigma_t} = 960$ GeV in the $W\gamma$ mode and the production of $\sigma_t$ is excluded in most of the mass range below 890 GeV in the $Z\gamma$ channel. Using the benchmark composite scalar model, the production of $\phi$ is excluded in most of the mass range below 1180 GeV for coupling scenario (b) described in text. The limits on the LSTC benchmark are more stringent than the previous results obtained at ATLAS and documented in Ref. [40].

Acknowledgements

We thank CERN for the very successful operation of the LHC, as well as the support staff from our institutions without whom ATLAS could not be operated efficiently.

We acknowledge the support of ANPCyT, Argentina; YerPhI, Armenia; ARC, Australia; BMWFW and FWF, Austria; ANAS, Azerbaijan; SSTC, Belarus; CNPq and FAPESP, Brazil; NERC, NRC and CFI, Canada; CERN; CONICYT, Chile; CAS, MOST and NSFC, China; COLCIENCIAS, Colombia; MSMT CR, MPO CR and VSC CR, Czech Republic; DNRF, DSNRC and Lundbeck Foundation, Denmark; EPLANET, ERC and NSRF, European Union; IN2P3-CNRS, CEA-DSM/IRFU, France; GNSF, Georgia; BMBF, DFG, HGF, MPG and AvH Foundation, Germany; GSRT and NSRF, Greece; ISF, MINERVA, GIF, I-CORE and Benoziyo Center, Israel; INFN, Italy; MEXT and JSPS, Japan; CNRST, Morocco; FOM and NWO, Netherlands; BRF and RCN, Norway; MNISR and NCN, Poland; GRCs and ICT, Portugal; MNE/IFA, Romania; MES of Russia and ROSATOM, Russian Federation; JINR; MSTD, Serbia; MSSR, Slovakia; ARRS and MIZŠ, Slovenia; DST/NRF, South Africa; MINECO, Spain; SRC and Wallenberg Foundation, Sweden; SER, SNSF and Cantons of Bern and Geneva, Switzerland; NSC, Taiwan; TAEK, Turkey; STFC, the
