ABSTRACT

We report on the quiescent state of the soft gamma repeater SGR 0501+4516 observed by XMM–Newton on 2009 August 30. The source exhibits an absorbed flux ~75 times lower than that measured at the peak of the 2008 outburst, and a rather soft spectrum, with the same value of the blackbody temperature observed with ROSAT back in 1992. This new observation is put into the context of all existing X-ray data since its discovery in 2008 August, allowing us to complete the study of the timing and spectral evolution of the source from outburst until its quiescent state. The set of deep XMM–Newton observations performed during the few years time-scale of its outburst allows us to monitor the spectral characteristics of this magnetar as a function of its rotational period, and their evolution along these years. After the first ~10 d, the initially hot and bright surface spot progressively cooled down during the decay. We discuss the behaviour of this magnetar in the context of its simulated secular evolution, inferring a plausible dipolar field at birth of 3 × 1014 G, and a current (magnetothermal) age of ~10 kyr.

Key words: pulsars: general – pulsars: individual: SGR 0501+4516 – X-rays: general.

1 INTRODUCTION

Magnetars are isolated neutron stars with a persistent X-ray emission of $L_X \sim 10^{34} - 10^{36}$ erg s$^{-1}$, rotating at spin periods of ~2–12 s and with large period derivatives (10$^{-13}$–10$^{-10}$ s s$^{-1}$) in respect to radio pulsars. Occasionally these objects also emit bursts and outbursts. Anomalous X-ray pulsars (AXPs) and soft gamma repeaters (SGRs) are two observational manifestations of magnetars. The radiation observed from these objects is believed to be powered by the decay of their strong magnetic fields (see Mereghetti 2008; Rea & Esposito 2011, for recent reviews).

SGRs are characterized by periods of activity during which they emit short bursts in the hard X-ray/soft gamma-ray energy range ($t \sim 0.1–0.2$ s; $L_X \sim 10^{38} - 10^{41}$ erg s$^{-1}$). In addition, they have been observed to emit intermediate flares, with typical durations of $t \sim 1–60$ s and luminosities of $L_X \sim 10^{41} - 10^{43}$ erg s$^{-1}$, and rarely giant flares ($t \sim 200–400$ s, and peak luminosities larger than ~4 × 10$^{44}$ erg s$^{-1}$; Mereghetti 2008 and references therein). The frequent short bursts are supposed to be associated either with small cracks in the neutron star crust due to magnetic diffusion or with tearing instabilities produced by the sudden loss of magnetic equilibrium, while the intermediate flares can arise from heating of the corona by magnetic reconnection in the stellar magnetosphere (Thompson & Duncan 1995; Lyubarsky 2002). The giant flares would be linked to global rearrangements of the magnetic field in the neutron stars magnetosphere and interior (Thompson & Duncan 1995).

Magnetar persistent X-ray emission is usually characterized by a soft (~0.5–10 keV) X-ray component interpreted as due to thermal photons emitted from the surface which undergo resonant cyclotron scattering on to mildly relativistic electrons flowing in the magnetosphere (Thompson, Lyutikov & Kulkarni 2002). In some cases, a hard X-ray component extending up to ~200 keV has been observed, possibly due to the same up-scattering process but on a population of more energetic electrons (Baring & Harding 2007; Beloborodov & Thompson 2007; Nobili, Turolla & Zane 2008; Beloborodov 2013). The soft X-ray component (on which this
paper focuses) is generally fitted with either a blackbody with a temperature \( kT \sim 0.3-0.6 \text{keV} \) and a power law with \( \Gamma \sim 2-4 \), or two blackbodies \( (kT_1 \sim 0.3 \text{keV} \) and \( kT_2 \sim 0.7 \text{keV}; \text{Mereghetti} \ 2008) \), while the hard X-ray component is modelled by a power-law spectrum of an index of \( \sim 0.5-1.5 \).

SGR 0501+4516 was discovered on 2008 August 22 by Swift-Burst Alert Telescope (BAT) in correspondence to a series of short X-ray bursts and intermediate flares (Barthelmy et al. \ 2008; Holland et al. \ 2008). X-ray pulsations at a period of 5.7 s were observed by RXTE (Gogus, Woods & Kouveliotou \ 2008) and an estimate of the surface dipolar magnetic field (at the pole) \( B \sim 2 \times 10^{14} \text{G} \) was obtained from its period and spin-down rate (Woods, Gogus & Kouveliotou \ 2008; Rea et al. \ 2009; Göğüş et al. \ 2010). Detailed studies of SGR 0501+4516 in the X-rays have been published by Rea et al. \ (2009), Göğüş et al. \ (2010) and Kumar, Ibrahim & Safi-Harb \ (2010). Radio observations did not reveal any emission in the first days after the beginning of the outburst (Gelfand et al. \ 2008; Hessels et al. \ 2008; Kulkarni & Frail \ 2008), remaining undetected afterwards. An optical/infrared counterpart has been identified (Fatkhullin et al. \ 2008; Rea et al. \ 2008a; Rol et al. \ 2008; Tanvir & Varricatt \ 2008). In addition, optical pulsations have been detected for SGR 0501+4516 (Dhillon et al. \ 2011).

In this paper, we present spectral and timing analysis of a new XMM–Newton observation of SGR 0501+4516 carried out 1 yr after the onset of the bursting activity which led to its discovery. In addition, we used all the existing data from XMM–Newton, Swift-X-ray Telescope (XRT), RXTE, Chandra and Suzaku to model the flux and the spin period evolution.

## 2 Observations and Reduction

### 2.1 XMM–Newton

The XMM–Newton Observatory (Jansen et al. \ 2001) observed SGR 0501+4516 again on 2009 August 30 (see Table 1) with the European Photon Imaging Camera (EPIC) instruments (pn and MOSs; Strüder et al. \ 2001; Turner et al. \ 2001).

This new observation was processed using SAS version 12.0.1 with the most up to date calibration files (CCF) available at the time the reduction was performed (2012 December). Standard data screening criteria were applied in the extraction of scientific products. Soft proton flares were not present, resulting in the total on-source exposure time of 37.8 ks (see also Table 1). For consistency, source and background events were also re-extracted for previous observations (see Table 1 and Fig. 1), using the same version of the standard software.

### 2.2 Other X-ray observations

To obtain an accurate timing solution we also extracted the events from observations carried out by other X-ray missions (see also Fig. 1). SGR 0501+4516 was first monitored with the Swift-XRT from 2008 August 26 until 2009 April 19, in windowed timing (WT) mode and for a total exposure of 436 ks (see Göğüş et al. \ 2010 for details). Later on, seven new observations were performed in photon counting (PC) mode from 2009 October 7 to 2010 February 21, and for a total exposure time of 38.5 ks. To extract all the events we used XSELECT as part of the HEASOFT package (version 6.13), and then converted all the event arrival times to the Solar system barycentre. For this we selected the same source position used for the XMM–Newton data set.

![Figure 1. The outburst decay of the persistent X-ray flux of SGR 0501+4516 fitted with a double exponential function (see also Section 4 for more details). We refer here as BAT trigger: MJD 54700.0 12:41:59.000 (UT). The fluxes are absorbed and in the 1–10 keV energy range.](http://mnras.oxfordjournals.org/)

### Table 1. Summary of all the available XMM–Newton observations of SGR 0501+4516 since the discovery outburst. The exposure time refers to the pn camera. Count rates are background corrected. The pulsed fraction is defined as the background subtracted (max − min)/(max + min) in the 0.3–12 keV energy band.

From 2008 August 22 to October 14 the source was monitored with RXTE-Proportional Counter Array (PCA), with a total exposure time of 82.4 ks in 29 observations (details in Göğüş et al. 2010). The source was also observed with the Advanced CCD Imaging Spectrometer (ACIS) and the High Resolution Camera (HRC) on board Chandra, on 2008 August 26 (36.5 ks) and September 25 (10 ks; see Göğüş et al. 2010 for a discussion). Suzaku observed SGR 0501+4516 with the X-ray Imaging Spectrometer (XIS) for ∼51 ks on 2008 August 26–27 (see Enoto et al. 2009). For all these observations source and background events were extracted, and was applied the barycentre correction at the source position.

3 TIMING ANALYSIS AND RESULTS

In order to produce a timing solution for the source covering the time interval over which data are available (MJD 54701.1–55248.6), we started from the solution determined by Rea et al. (2009). We considered data obtained by Swift-XRT, XMM–Newton-EPIC-pn and Suzaku, RXTE-PCA and Chandra covering the first ∼160 d (interval MJD 54701.1–54859.5). We folded all the available observations around the best period they determined, \( P(T_0) = 5.7620695 \) s, where \( T_0 = 54701.0 \) MJD, sampling the profiles so obtained in 12 bins. The phases of the profiles were obtained from a sinusoidal fit of the profile. We note that only phases evaluated from profiles detected at a significance larger than 2\( \sigma \) were collected. On top of a strong noise component affecting the pulse phases (which leads to a high value of the \( \chi^2 \) ∼7.8), we found that a second derivative significantly improves the modelling with respect to a fit with a quadratic function (see leftmost column of Table 2), compatible with the results quoted by Rea et al. (2009).

Finally, to obtain a timing solution for the whole interval (∼548 d) we added the new observations during quiescent state. We point out that the uncertainty on the resulting parameters, and in particular that affecting the second derivative, prevents to unequivocally phase connect the observations obtained by XMM–Newton and Swift in quiescence (after MJD 55073.616). Nevertheless, we tentatively phase connect these observations, considering the solution giving the lower value of residuals as the most probable one. The best solution quoted in the rightmost column of Table 2 has a \( \chi^2 \) lower by 104, for 92 degrees of freedom, with respect to the second best. However, we stress that the solution is not unique, since the phase connection is not warranted by the available data, and its validity relies on the choice of the particular functional form used to model the phase evolution (a cubic polynomial in this case). We also note that the second derivative of the spin period takes a value which is roughly one order of magnitude smaller than that obtained considering only the first 159 d of the outburst. The best-fitting solution and timing residuals are plotted in Fig. 2.

According to this timing solution, the spin period evaluated at the beginning of the 2009 August XMM–Newton observation (MJD 55073.61477) is \( P_{XMM} = 5.7622571(2) \) s. To check this estimate, we compared this value with that obtained by performing an epoch folding search analysis (Leahy 1987) over the XMM–Newton data set alone, considering 20 phase bins to sample the oscillation. The value that we have obtained (5.762253(8) s) is compatible with that predicted by the tentative timing solution listed in Table 2, even if its larger uncertainty with respect to the value obtained from phase fitting makes it compatible with more than one possible timing solution.

By fitting a fifth-order polynomial to the phases observed in the interval MJD 54700.794–54940.953, Göğüş et al. (2010) estimated a spin period of 5.762096529(1) at MJD 54750.0. Evaluating our solution at that epoch yields instead an estimate of 5.76209578(4) s. The significant difference between the two solutions is most probably due to the different model used in the fit of the pulse phases. In presence of a strong timing noise component, like in this case, a higher order polynomial is able to follow more closely the variations of the pulse phase on short time-scale, which has a significant effect on the value of the spin period evaluated at each epoch.

In the new XMM–Newton observation we find that the 0.3–12 keV pulse profile consists of a main peak from phases ∼0.3–1.0 divided into two subpulses at phase ∼0.65, and with a flatter region between phases ∼0 and 0.3. At lower energies, the two subpulses seem to merge into one single peak as the energy increases (see Fig. 3). We also computed the pulsed fraction as \( \text{max}(\text{min})/(\text{max} + \text{min}) \), obtaining a value of 45(6) per cent (see also Table 1). As seen in the previous five XMM–Newton observations, both the pulse shape and the pulsed fraction change as a function of energy (see Figs 3 and 4).

4 SPECTRAL ANALYSIS AND RESULTS

To obtain the 0.5–10 keV phase-averaged spectrum for the new XMM–Newton observation we used source and background photons extracted as described in Section 2. Then, the response matrix was...
Figure 3. Top panel: pulsed fraction dependence with energy for the previous five XMM–Newton observations and the one during quiescence. In both panels the black, red, light green, dark blue, cyan and magenta colours refer to the six observations ordered by increasing epoch. Bottom panel: pulse profiles of the same observations in the same energy band (see also a single profile during quiescence in Fig. 7).

created for that observation. For the present analysis we used the XSPEC package (version 12.7.0).

The spectrum during quiescence was well fit by an absorbed blackbody (BB) + power law (PL) model. Neither a single BB nor a PL gave an acceptable fit. For the photoelectric absorption we used the cross-sections from Balucinska-Church & McCammon (1992), and the solar abundance from Anders & Grevesse (1989). The best-fitting parameters for the absorbed BB+PL model are $N_H = 0.85(3) \times 10^{22}$ cm$^{-2}$, $kT = 0.52 \pm 0.02$ keV and $\Gamma = 3.87 \pm 0.13$ (reduced $\chi^2 = 1.06$ for 165 dof). In Table 3 we display the main spectral parameters obtained with this new XMM–Newton observation. We also show for comparison the results at the peak of the 2008 outburst (see also Fig. 6).

Comparing our results with the measurements reported in Göğüş et al. (2010) for Swift-XRT observations at the very end of 2009 and starting 2010, we note that their photon index (5.04 ± 0.21) is steeper than the value found in the present study (3.84 ± 0.06). However, in Göğüş et al. (2010) the Swift-XRT spectra were extracted using observations of ~12 ks, three times lower than the exposure time of this new XMM–Newton observation (see Table 1), plus the fact that the XMM–Newton EPIC-pn camera has an effective area larger than the Swift-XRT one (~10). We made an attempt to reconcile these results by freezing the hydrogen column density to the value obtained by Göğüş et al. (2010) (~1.19 × 10$^{22}$ cm$^{-2}$). We obtained a photon index of 5.59 ± 0.13, but the reduced $\chi^2$ increased

$^a$Model: absorbed BB+PL; reduced $\chi^2$ (dof) = 1.15 (371); $N_H = 0.88(1) \times 10^{22}$ cm$^{-2}$.

$^b$Fluxes are unabsorbed in the 0.5–10 keV range (unless specified), and in units of 10$^{-11}$ erg cm$^{-2}$ s$^{-1}$.

Table 3. Parameters for the spectral modelling of the phase-averaged spectrum of SGR 0501+4516 for the XMM–Newton observation during quiescence. We also show for comparison the results for a XMM–Newton observation at the peak of the 2008 outburst. Errors are at the 90 per cent confidence level.

$^a$Model: absorbed BB+PL; reduced $\chi^2$ (dof) = 1.15 (371); $N_H = 0.88(1) \times 10^{22}$ cm$^{-2}$.

$^b$Fluxes are unabsorbed in the 0.5–10 keV range (unless specified), and in units of 10$^{-11}$ erg cm$^{-2}$ s$^{-1}$.
up to 1.84 (165 dof) and the residuals showed a strong sinusoidal structure. Furthermore, we have fit the Swift-XRT spectrum with the \( N_\text{H} \) fixed at the XMM–Newton best-fitting value. We obtained a photon index \((3.7 \pm 0.9)\) consistent with the XMM–Newton one, and an acceptable fit (reduced \( \chi^2 = 1.1 \) for 78 dof). Therefore, the discrepancy may be explained due to the lower statistics of the Swift-XRT spectra with respect to our XMM–Newton EPIC-pn observation.

In addition, the averaged spectra showed an excess in the residuals at energies larger than 8 keV (see Fig. 5), that Rea et al. (2009) suggested to be due to the presence of the same hard X-ray component detected by INTEGRAL. However, the addition of a second PL component was not significant.

To study the spectral evolution of SGR 0501+4516 since the 2008 August 22 outburst, we fitted simultaneously the spectra of all the XMM–Newton observations again with a BB+PL model (see Fig. 5), leaving all parameters free except \( N_\text{H} \) which was constrained to be the same in all observations (final reduced \( \chi^2 = 1.17 \) for 1011 dof; see also Rea et al. 2009). The values of the spectral parameters were not significantly different when modelling each observation separately. The measured hydrogen column density is \( N_\text{H} = 0.893(8) \times 10^{22} \text{ cm}^{-2} \), and the absorbed flux in the 0.5–10 keV band varied from 4.1 to 0.3 \( \times 10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2} \) (see also Table 3), corresponding to a luminosity range of \( 1.2–0.10 \times 10^{35} \text{ d}^{-2.5} \text{ erg s}^{-1} \), where \( \text{d}_{2.5} \) is the source distance in units of 2.5 kpc (see Fig. 6).

Moreover, we have tried more sophisticated models, the resonant cyclotron scattering (RCS; Rea et al. 2008b) and the NTZ (the 3D evolution of the RCS model; Nobili et al. 2008; Zane et al. 2009), but this resulted in poorer fits with respect to the BB+PL.

Rea et al. (2009) found evidence that as the flux decreased the X-ray spectrum softened during the first month after the bursting onset. In this new observation, SGR 0501+4516 exhibited an even softer spectrum and a flux \( \sim 75 \) times lower than that measured during the outburst. A similar behaviour was observed with ROSAT back in 1992 (Rea et al. 2009). This result is also consistent with the results obtained by Göğüş et al. (2010) using Swift-XRT data. Fitting the flux evolution in the first 548 d after the onset of the bursting activity, we found that a double exponential function of the form \( \text{Flux}(t) = K_0 + K_1 \exp^{-t/t_{c1}} + K_2 \exp^{-t/t_{c2}} \) provided the best (although not completely satisfactorily) representation of the data (see Fig. 1; reduced \( \chi^2/\text{dof} = 5.7/51 \)); the best values of the parameters are \( K_0 = 0.16 \times 10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2} \) (fixed), \( K_1 = 3.2(8) \times 10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2} \) and \( K_2 = 0.84(8) \times 10^{-11} \text{ erg s}^{-1} \text{ cm}^{-2} \), and \( t_{c1} = 21.5(7) \) and \( t_{c2} = 220(20) \) d. This is similar to the outburst decays of other magnetars, usually fitted by two components (see Rea et al. 2009 and references therein).

### 4.1 Phase-resolved spectroscopy

We performed a phase-resolved spectroscopy (PRS) for the new XMM–Newton observation. We generated 10 phase-resolved spectra for this observation using the ephemeris reported in Section 3. An absorbed BB+PL model provided a good fit for all 10 phase-resolved spectra during quiescence. A simple absorbed BB or PL models did not yield acceptable fits. In Fig. 7 we have plotted the parameters derived from the PRS analysis. In general, the spectral parameters follow the trend seen during the outburst. The power-law photon index becomes softer between phases \( \sim 0.0–0.4 \), and the blackbody temperature remained rather constant.

The pulse profiles and the spectral changes in phase and time can be globally analysed by carrying out dynamic spectral profiles (DSPs). In Fig. 8 we show DSPs for two XMM–Newton observations, at the peak of the 2008 outburst (panels on the left) and during quiescence (panels on the right). Each panel shows a contour plot of the \( vF_\nu \) flux as a function of phase and energy, and has been derived from the 10 extracted phase-resolved spectra. The top panels correspond to the total flux, using the BB+PL model, while middle bottom panels show, respectively, the flux of the PL and BB components. The new XMM–Newton observation during quiescence confirms the evolutionary trend of the phase-dependent spectrum during the outburst, with the PL component dominating the emission at all the times at energies above \( \sim 5 \text{ keV} \). However,
the main component of the profiles was dominated by the BB component (see also Fig. 7).

To study whether the X-ray spectrum of SGR 0501+4516 has any phase-dependent absorption feature, similar to the one detected in SGR 0418+5729 (Tiengo et al. 2013), we produced energy versus phase images for all the available XMM–Newton observations by binning the source counts into 50 phase bins and energy channels of 200 eV (and then divided by the average number of counts in the same energy bin). The resulting images can be seen in Fig. 9. Some hints for two narrow dark stripes, indicating a possible phase-variable feature, seem to be visible at the two sides of pulse maximum in early observations. However, these deviations from the phase average spectrum are much smaller than in SGR 0418+5729 and could not be significantly detected by fitting the corresponding phase-resolved spectra.

5 DISCUSSION AND CONCLUSIONS

In this paper we presented an X-ray study of the spectral and timing properties of SGR 0501+4516 during quiescence, using a new XMM–Newton observation obtained on 2009 August 30. We also made use of this new observation to improve the modelling of the outburst and the spin period evolution of the source since it was first detected in 2008 August 22. To do this we used all the available data collected up to date from XMM–Newton, Swift-XRT, RXTE, Chandra and Suzaku.

During quiescence both the pulse shape and the pulsed fraction change as a function of energy. The 0.3–12 keV pulse profile consists mainly of a single peak showing no very prominent features. At lower energies the pulse profile presents two peaks that seem to get dissolved into one as the energy increases. Moreover, the pulsed fraction increases at any given energy range as the outburst evolves (see Fig. 3).

The spectrum was well fit by an absorbed BB+PL model. The best-fitting parameters for this model are $N_H = 0.85(3) \times 10^{22} \text{ cm}^{-2}$, $kT = 0.52 \pm 0.02 \text{ keV}$ and $\Gamma = 3.87 \pm 0.13$. The source shows an absorbed flux $\sim 75$ times lower than that measured during the 2008 outburst, and a rather soft spectrum, with the same value of the blackbody temperature observed with ROSAT back in 1992 and with Swift-XRT in 2009–2010. The 0.1–2.4 keV observed flux was $F_X \sim 1.8 \times 10^{-12} \text{ erg cm}^{-2} \text{ s}^{-1}$, in line with that observed by ROSAT before the outburst.

All magnetar outbursts detected so far were characterized by the presence of a hotspot, which cools down until quiescence is reached; the peak luminosity is of the order of a $10^{35-36} \text{ erg s}^{-1}$ (see Pons & Rea 2012). Magnetar outbursts are believed to be due to a sudden crustal crack consequence of their unstable magnetic field configuration, when the twisted magnetic field in its constant movement towards a stable/quiet assessment, stresses the crust.
Figure 9. Energy versus phase images obtained by binning the XMM–Newton-EPIC-pn source counts into 50 phase bins and energy channels of 200 eV. The double red arrow (identical for the first five observations) indicates that dark stripes, resembling the phase-variable absorption line detected in SGR 0418+5729 (Tiengo et al. 2013), are possibly present in the first observations.

Figure 10. Magnetothermal evolution of a neutron star with initial magnetic field $3 \times 10^{14}$ G (at the pole): from left to right, period, period derivative, evolution in the $P–\dot{P}$ diagram and the thermal bolometric luminosity. The dashed lines and the asterisk mark the observed timing properties of SGR 0501+4516. The band in the luminosity plot reflects the distance uncertainty, while the band in the timing properties corresponds to the uncertainty of the inclination angle in the theoretical model. In the third panel, the solid lines represent the real ages $t = 1, 10$ and 100 kyr.

until its breaking point. The large amount of energy that is released in this event is expected to be of the order of $\sim 10^{42-44}$ erg. Part of this energy will heat the crust (explaining the sudden increase of the surface temperature soon after the outburst onset), part of it will be spent in accelerating particles in the magnetosphere (explaining the hardening of the spectral shape), and a large fraction will be released in neutrinos. The limiting luminosity is a consequence of the neutrino emission that regulates the release of most of the energy dumped in the crust as soon as a temperature reaches here a value of $4 \times 10^9$ K (Pons & Rea 2012). The total energy released by SGR 0501+4516’s outburst in the $0.5-10$ keV band is $\sim 2 \times 10^{41}$ erg, in line with what expected for a typical large-scale crustal event. On the other hand, all typical outburst characteristics were observed for SGR 0501+4516 (see Section 4), as well as a clear dependence on the rotational phase of the crustal heating, which was localized in a few degrees of surface, creating a localized hotspot, possibly on the magnetic pole, which cooled down until its quiescent emission level.

The long-term magnetothermal evolution, simulated with the Viganò, Pons & Miralles (2012) code, indicates that this source is consistent with being born $\sim 10$ kyr ago (not too far from its 16 kyr characteristic age) with an initial dipolar magnetic field of $3 \times 10^{14}$ G. This exact value depends, by a factor of $<2$, on the parameters of the neutron star (mass, radius, inclination angle) and on the poorly known internal magnetic configuration. In Fig. 10, we show the evolution of period, period derivative, the source track in the $P–\dot{P}$ diagram and the thermal, bolometric luminosity.

As generally found in magnetars, the temperature inferred from the BB+PL fit is of the same order of, although somewhat higher than, what predicted by the evolutionary model (100–200 eV, depending on the details and the internal geometry). The mismatch (by a factor of $\sim 2-3$) is well within what can be expected from the assumptions of both the emission and evolution models. It is known that spectral fitting with resonant Compton scattering models results in a lower temperature, closer to that of the cooling models, even keeping the assumption of blackbody seed photons.
Actually, thermal radiation from the star surface is likely different from a simple blackbody, because of local reprocessing by some sort of atmosphere or, on the contrary, because the surface is in a condensed state. Moreover, the hotspot temperature is not uniform and geometrical effects (viewing angle, inclination of the magnetic axis) come into play; these are not accounted for as yet. Given these uncertainties, we rather compare the luminosity, which depends on the distance, but not much on the details of the model.

We note that this source belongs to a vast group of magnetars (1E 1547−5408, SGR 1627−41, SGR 1835−0943, 4U 0142+614, +1978–052, CXO 1647−4552), which timing properties are linked by the same evolutionary track, compatible with being born with an initial field of $2−3 \times 10^{14}$ G, as discussed in Viganò et al. (2013). In this scenario, most magnetars are born with a narrow range of magnetic field values, and the timing and spectral differences between them are due only to their particular ages.

We have also compared the observed outburst decay with the detailed theoretical model presented in Pons & Rea (2012), and used to reproduce the outburst decay of other magnetars (Rea et al. 2012, 2013). Starting with a neutron star with $B = 2 \times 10^{14}$ G and the crust temperature fixed to reproduce the flux observed by ROSAT in 1992 at the estimated distance, we simulate the starquake by injecting $1.5 \times 10^{52}$ erg in the crust layer between $7 \times 10^{9}$ and $4 \times 10^{10}$ g cm$^{-3}$ in a polar cap of about $30^\circ$ around the pole. We then follow the thermal evolution of the crust until it returns to the original state. The results are shown in Fig. 11, where we compare the theoretical model with the XMM–Newton observations.
